### Acknowledgements

Throughout the course of this thesis effort, many people have assisted in its completion. I would like to take this opportunity to express my gratitude to those who have contributed to the culmination of the research I have conducted during my graduate education.

First, I would like to express my gratitude to Captains Kevin Sheehan, Greg Gross, Bruce Acker, and Lieutenant Bruce Clough for the synergistic effect of our concurrent study of controlling the STOL F-15 aircraft. Our morning "coffee sessions" proved to be an invaluable forum for discussing problems and reflecting on possible approaches to solve those problems. Another person who has had a profound impact on my thesis effort is my advisor, Dr. Peter S. Maybeck. I have found Dr. Maybeck to be an "educator" in the truest sense of the word. His interest, patience, and guidance have been inspirational. Finally, I wish to express my deepest gratitude to my wife Olga for her constant support during the years I have spent pursuing my education.

— Robert Houston

Abstract

A robust controller for the STOL F-15 aircraft is developed using the LQG/LTR (linear system model, quadratic cost, gaussian models of uncertainty used for controller synthesis, with loop transfer recovery techniques of tuning the filter in the loop for control robustness enhancement) methods. Full state feedback controllers are synthesized using CGT/PI (Command Generator Tracking feedforward compensator to provide direct incorporation of flying qualities into the design process, with proportional plus integral feedback control) synthesis, using implicit model following techniques to improve full state robustness characteristics. Finally, a Kalman filter is used to replace the unrealistic assumption of full state availability with estimated states, using a LTR scheme to recover as much full state robustness characteristics as possible.

# AN LQG UP-AND-AWAY FLIGHT CONTROL DESIGN FOR THE STOL F-15 AIRCRAFT

## I. Introduction

### 1.1 Background

The initial approach used to design aircraft control systems involved a mixture of classical single-input/single-output (SISO) control design techniques and engineering insight. In the past this has been effective, providing that the designer had sufficient intuition and was willing to carry the design process through enough single loop iterations to meet specifications. However, as airframes became more complex and control surfaces more numerous, this method became unwieldy, creating a need for multiple-input/multiple-output (MIMO) controller synthesis techniques. One school of thought emerging from this need is the extension of classical techniques to the MIMO case, thereby taking advantage of frequency domain theory developed by Bode, Nyquist, and Hurwitz (24). A second approach to MIMO controller design involves time domain techniques, which, assuming that the plant can be modeled as linear, can be readily coupled with linear system theory to yield a procedure which can be implemented on digital computers. Although both of the previously mentioned MIMO design philosophies have adamant supporters, they are really two

sides of the same coin, so neither should be abandoned for the other.

A design method which incorporates both the ease of implementation associated with time domain techniques and the invaluable stability information obtained from frequency domain analysis is the Linear-Quadratic-Gaussian (LQG) (11; 12) approach coupled with Loop Transfer Recovery (LTR) (5; 9; 13; 22). A more specific formulation using LQG synthesis methods, which is especially attractive for flight control applications, is Command Generator Tracking (CGT) combined with a regulator (R) designed via LQG methods; this is often denoted as a CGT/R design (12:151-166). This method yields a controller capable of incorporating handling qualities directly into the design process, while rejecting specified disturbance inputs. A more useful formulation of the CGT technique would include a proportional plus integral (PI) controller in a closed loop law incorporating a CGT precompensator in order to achieve type 1 characteristics; this is designated as a CGT/PI controller. However, as will be discussed later, problems have been encountered in the design of the full CGT/PI controller when a filter is embedded in the control loop and LTR techniques are applied to achieve a robust controller. Therefore, in some applications, CGT/R and CGT/PI designs might both be pursued by means of LQG/LTR techniques.

## 1.2 Problem

The objective in this study is to design a robust tracker controller for the STOL F-15 aircraft using digital Command Generator Tracking to incorporate specified aircraft handling qualities into the design process. This controller will be designed via LQ methods using implicit model following to enhance robustness (16). Kalman filtering techniques will be used to replace full state feedback with state estimates. The robust tracker controller will be designed to maintain aircraft stability (and as desirable performance as possible) in the face of large parameter variations such as control actuator failure, mismodeled actuator dynamics, and actuator saturations. This study will also address the robustness degradation due to reducing the order of the aircraft model and also due to operating the aircraft at a different point in its operational envelope than that used for controller design. The feasibility of using the LTR tuning method developed by Doyle and Stein (5; 22) in a CGT/PI controller will also be investigated.

It is not an objective of this thesis to engage in a debate over the adequacy of existing MIMO controller synthesis techniques; however, several methods of addressing the same STOL F-15 problem will be carried out concurrently with this study (1; 20), in the hope that a

comparison of the obtained results will prove useful in constructing logical approaches to similar problems.

### 1.3 Scope

This thesis effort will encompass the LQG/LTR design and analysis of a CGT/PI/KF longitudinal flight control system for the STOL F-15 aircraft. Specifically, the added aerodynamic surfaces of the STOL version of the F-15 are exploited to accomplish a pitch pointing maneuver at 4 points within the aircraft's combat envelope. Further, a complete robustness enhancement/analysis of the controller designed at the "nominal" flight condition of Mach 0.9 at 20,000 feet will be carried out. Such topics as plant variations, control derivative variations, noise corruption of plant states, throttle gain scheduling, control surface failures, measurement noise corruption, and impact of LTR tuning on a PI controller design will be addressed. A nonlinear analysis of the controller design, specifically admitting both position and rate limit saturations of actuators, will be carried out using Monte Carlo analysis software designed as a part of this thesis effort.

### 1.4 Assumptions

The physical description of an aircraft's dynamics can be represented by a set of nonlinear differential equations. Although these equations present a very accurate portrayal of the true aircraft, they fail to be useful in

designing control systems due to the tremendous computational loading incurred for a relatively small improvement in performance compared to controllers based on linearized aircraft equations of motion. Therefore, for the purposes of the designs accomplished in this study, perturbation equations, linearized about specific trim conditions, will be assumed adequate for the design models representing the STOL F-15 aircraft's equations of motion. A further assumption which will be made is that all noise corruptions in both the system and measurement models will be adequately modeled as white and Gaussian. Although a true white noise would contain infinite power, the assumption of white noise physically implies that colored, i.e. time correlated, noises affecting the system will appear white over the bandpass of interest in the aircraft dynamics (11). The assumption of Gaussianity can be justified by invoking the central limit theorem of probability theory (11; 18). The above mentioned assumptions are considered major in that they are a significant influence on the entire thesis. Other assumptions made throughout the remainder of this study are of less global impact; therefore, these will be presented only as needed for specific development. Although wind buffet rejection in the CGT controller is not addressed, this could be accomplished, if desired, using the same methodology.

### 1.5 Sequence of Presentation

The material contained in this thesis is presented in such a manner as first to build a theoretical framework and then to use the developed control synthesis techniques in a specific application. Chapter II presents CGT/R and CGT/PI controller forms and discusses the advantages and disadvantages of each. Chapter III introduces the equations of motion and the model for the STOL F-15 aircraft. Chapter IV is concerned with stability and robustness enhancement of the controllers discussed in Chapter II. Chapter V is the culmination of the preceding three chapters; in this chapter controller designs are carried out and evaluated using existing and designed computer aided design software (7; 16; 17). Finally, Chapter VI presents conclusions of the research conducted and recommendations for further study.

## II. LQG Theoretical Development

### 2.1 Introduction

This chapter is intended to serve as an introduction to the theoretical foundation upon which the controller design of Chapter V is based. It is assumed that the reader has had an upper division undergraduate or a first year graduate level course in classical control theory (4) and has a knowledge of modern optimal control which includes basic LQG techniques and Kalman filtering (11; 13). Any further material considered substantive to a full understanding of Chapter V will be presented herein.

The remaining sections contained in this chapter develop four interrelated concepts. First, a derivation of LQG regulators will be presented. Shortcomings of this form of controller will be discussed as a motivation for the subsequent section on proportional plus integral controllers designed via LQG methods. Section 2.4 is intended to give the reader a conceptual introduction to model following design techniques. Thus, it yields a coherent transition into Section 2.5 which introduces Command Generator Tracking theory and its closed loop application with both regulator and PI controller forms.

As a final statement before embarking on the theoretical sections of this chapter, the reader should be

aware that the following derivations, although functionally complete, are not intended to be mathematically rigorous. Those who desire more theoretical detail are directed to References 11 and 12. However, this thesis is directed toward engineering application, and consequently derivations will be intended for the practicing engineer.

## 2.2 Synthesis of LQG Regulators

This section presents regulator design via LQG synthesis techniques. The following derivation is taken primarily from Reference 13 with exceptions as noted.

Consider the linear, discrete time, vector valued, stochastic difference equation

$$\underline{x}(t_{i+1}) = \underline{\phi}(t_{i+1}, t_i) \underline{x}(t_i) + \underline{B}_d(t_i) \underline{u}(t_i) + \underline{G}_d(t_i) \underline{w}_d(t_i) \quad (2-1)$$

where

$\underline{x}$  is an n-dimensional state vector,

$\underline{\phi}$  is an nxn state transition matrix,

$\underline{u}$  is an r-dimensional control deterministic control input,

$\underline{B}$  is an nxr input matrix, and

$\underline{w}_d$  is a discrete-time Gaussian noise sequence completely characterized by

$$E\{\underline{w}_d(t_i)\} = \underline{0} \quad (2-2)$$

and

$$E\{\underline{w}_d(t_i) \underline{w}_d^T(t_j)\} = \underline{Q}_d \delta_{ij} \quad (2-3)$$

where  $\underline{Q}_d$  is the covariance of the noise sequence, and  $\delta_{ij}$  is the Kronecker delta function.

Although a discrete system of the above form could arise naturally, in flight control applications, and many other applications as well, this model would be an equivalent discrete-time representation for an underlying continuous system (11:133,192). A stochastic differential equation which could be used to describe such an underlying continuous system would be

$$\dot{\underline{x}}(t) = \underline{F}(t)\underline{x}(t) + \underline{B}(t)\underline{u}(t) + \underline{G}(t)\underline{w}(t) \quad (2-4)$$

where  $\underline{w}(t)$  is zero-mean white Gaussian noise with a covariance

$$E\{\underline{w}(t)\underline{w}^T(t+\tau)\} = \underline{Q}\delta(\tau) \quad (2-5)$$

where  $\delta(\tau)$  is the Dirac delta function.

The discrete-time input matrix  $\underline{B}_d$  and the noise strength  $\underline{Q}_d$  of Equation (2-1) can be derived from the underlying continuous system model parameters by the relations (11):

$$\underline{B}_d(t_i) = \int_{t_i}^{t_{i+1}} \underline{\Phi}(t_{i+1}, \tau) \underline{B}(\tau) d\tau \quad (2-6)$$

and

$$\underline{Q}_d(t_i) = \int_{t_i}^{t_{i+1}} \underline{\Phi}(t_{i+1}, \tau) \underline{G}(\tau) \underline{Q}(\tau) \underline{G}^T(\tau) \underline{\Phi}^T(t_{i+1}, \tau) d\tau \quad (2-7)$$

respectively.

For the LQG regulator it is desired that certain linear combinations of the state variables, designated control variables, be regulated to zero. In the case of flight controller design, linearized models are used, and the perturbation control variables are linear combinations of perturbation states; regulating these perturbation variables to zero is equivalent to driving the aircraft back to the specific trim condition used for the basis of the linearized equations (6:154,165). These variables are represented by the p-dimensional vector  $\underline{y}_c$  defined by

$$\underline{y}_c(t) = \underline{C}(t)\underline{x}(t) \quad (2-8)$$

where  $\underline{C}$  is a p $\times$ n output matrix. A direct transmission term ( $\underline{D}(t)\underline{u}(t)$ ) in equation (2-8) would create cross-coupling between the states and the control inputs in the quadratic cost function; however, no generality is lost due to the omission of this term, as will be shown subsequently.

As an initial attempt to produce an optimal control function  $\underline{u}(t)$ , consider minimization of a cost function of the form

$$J = E \left\{ \sum_{i=0}^N \frac{1}{2} (\underline{y}_c^T(t_i) \underline{y}(t_i) \underline{y}_c(t_i) + \underline{u}^T(t_i) \underline{u}(t_i) \underline{u}(t_i)) + \frac{1}{2} (\underline{y}_c^T(t_{N+1}) \underline{y}_f \underline{y}_c(t_{N+1})) \right\} \quad (2-9)$$

where  $\underline{Y}(t_i)$  and  $\underline{Y}_f$  are  $p \times p$  symmetric weighting matrices on the control variables at time  $t_i$  and the final time  $t_f$ , respectively. These matrices are both chosen to be positive definite under the assumption that there should exist a cost associated with any control variable deviation from zero, or deviation from trim conditions for aircraft perturbation variables.  $\underline{U}(t_i)$  is an  $r \times r$  symmetric positive definite weighting matrix on the control inputs; in this case the weighting is chosen positive definite in order to avoid a controller which attempts to expend infinite control energy.

The magnitudes of  $\underline{Y}$  and  $\underline{U}$  are chosen relative to one another. If  $\underline{Y}$  is chosen larger, tighter control of the state trajectories is achieved. If  $\underline{U}$  is chosen larger, less control "energy" can be expended.

The cost minimizing control function  $\underline{u}^*(t_i)$  can be shown to be a linear function of the system states

$$\underline{u}^*(t_i) = -\underline{G}_C^*(t_i)\underline{x}(t_i) \quad (2-10)$$

Note that Equation (2-10) makes the unrealistic assumption that all of the system state variables will be accessible. A more practical assumption would incorporate a measurement model consisting of incomplete, noise corrupted measurements as follows (11:203,225):

$$\underline{z}(t_i) = \underline{H}(t_i)\underline{x}(t_i) + \underline{v}(t_i) \quad (2-11)$$

In the above equation  $\underline{v}(t_i)$  is a zero-mean Gaussian  $m$ -dimensional noise sequence with covariance  $\underline{R}(t_i)$  and  $\underline{H}$  is an  $m \times n$  measurement matrix. It is assumed that  $\underline{v}$  is independent of the discrete dynamics model noise  $\underline{w}_d(t_i)$  of Equation (2-1) (11:203,225).

In light of Equation (2-11), the optimal control function described by Equation (2-10) would seem to be little more than a mathematical abstraction, void of any practical engineering application; however, this is not the case. Under the LQG assumptions, certainty equivalence may be invoked (12:24,45); thus, the optimal control feedback weighting matrix,  $\underline{G}_C^*$ , for a nondeterministic system with only partial, noise-corrupted state measurements available, can be derived under the assumption of a deterministic system model with access to all states. Once derived, this optimal gain may be cascaded with a Kalman filter in order to produce an optimal stochastic control of the following form:

$$\underline{u}^*(t_i) = -\underline{G}_C^*(t_i) \hat{\underline{x}}(t_i^+) \quad (2-12)$$

The optimal gain function,  $\underline{u}^*$ , can be obtained by solving for the optimal gain  $\underline{G}_C^*(t_i)$  as a function of the backward Riccati recursion difference equation for the matrix  $\underline{K}_C$ :

$$\begin{aligned} \underline{G}_C^*(t_i) &= (\underline{U}(t_i) + \underline{B}_d^T(t_i) \underline{K}_C(t_{i+1}) \underline{B}_d(t_i))^{-1} \\ &\cdot (\underline{B}_d^T(t_i) \underline{K}_C(t_{i+1}) \underline{\phi}(t_{i+1}, t_i)) \quad (2-13) \end{aligned}$$

where

$$\begin{aligned} \underline{K}_C(t_i) &= \underline{X}(t_i) + \underline{\phi}^T(t_{i+1}, t_i) \underline{K}_C(t_{i+1}) \\ &\cdot (\underline{\phi}(t_{i+1}, t_i) - \underline{B}_d(t_i) \underline{G}_C^*(t_i)) \quad (2-14) \end{aligned}$$

(Note that  $\underline{K}_C$  has been constructed in order to provide tractability in the solution for the optimal gain matrix and bears no relation to the Kalman filtering gain  $\underline{K}$ .)

Since Equation (2-14) is a backward running equation, the solution must be generated from a terminal condition defined as

$$\underline{K}_C(t_{N+1}) = \underline{X}_f = \underline{C}^T(t_f) \underline{Y}_f \underline{C}(t_f) \quad (2-15)$$

This completes the formulation of the simple LQG regulator; however, an important problem which has not yet been addressed is the need to exert effective sample data control over a continuous system, not only at each sample time, but between sample times as well.

Consider a flight control application in which a digital controller is implemented to maintain stable flight in a statically unstable flight mode. If the sampling rate of the controller is less than approximately five times the Nyquist rate, the aircraft could go unstable between

sample times. For flight controller design, the initial and terminal transients of an LQG controller for a time-invariant system subjected to stationary noises, and designed using constant weighting matrices, can be considered negligible in comparison to the length of time that the aircraft is in steady state conditions. Consequently, the controller gains  $\underline{G}_C^*$  matrices (as well as any Kalman filter gains which might be associated with the system) become constants.

An appropriate quadratic cost function which incorporates a continuous weighting of the system states and control inputs is

$$J_C = E \left\{ \frac{1}{2} \underline{x}^T(t_{N+1}) \underline{X}_f \underline{x}(t_{N+1}) + \sum_{i=0}^N \left( \int_{t_i}^{t_{i+1}} \frac{1}{2} (\underline{x}^T(t) \underline{W}_{xx}(t) \underline{x}(t) + \underline{u}^T(t) \underline{W}_{uu}(t) \underline{u}(t) + 2 \underline{x}^T(t) \underline{W}_{xu}(t) \underline{u}(t)) dt \right) \right\} \quad (2-16)$$

where  $\underline{W}_{xx}(t)$  is positive semidefinite, so some states may not have a cost associated with them if desired, and  $\underline{W}_{uu}(t)$  is positive definite for all  $t$  for the same reason as discussed for  $\underline{U}(t_i)$ . Upon dividing this function into  $n+1$  control intervals over  $(t_0, t_{N+1})$ , the cost function becomes

$$J_C = E \left\{ \frac{1}{2} \underline{x}^T(t_{N+1}) \underline{X}_f \underline{x}(t_{N+1}) + \sum_{i=0}^N \frac{1}{2} [\underline{x}^T(t_i) \underline{X}(t_i) \underline{x}(t_i) + \underline{u}^T(t_i) \underline{U}(t_i) \underline{u}(t_i) + 2 \underline{x}^T(t_i) \underline{S}(t_i) \underline{u}(t_i)] \right\} \quad (2-17)$$

where

$$\underline{x}(t_i) = \int_{t_i}^{t_{i+1}} \underline{\phi}^T(t, t_i) \underline{W}_{xx}(t) \underline{\phi}(t, t_i) dt \quad (2-18)$$

$$\begin{aligned} \underline{U}(t_i) = & \int_{t_i}^{t_{i+1}} [\underline{\bar{B}}^T(t, t_i) \underline{W}_{xx}(t) \underline{\bar{B}}(t, t_i) + \underline{W}_{uu}(t) \\ & + \underline{\bar{B}}^T(t, t_i) \underline{W}_{xu}(t) + \underline{W}_{xu}^T \underline{\bar{B}}(t, t_i)] dt \end{aligned} \quad (2-19)$$

$$\underline{S}(t_i) = \int_{t_i}^{t_{i+1}} [\underline{\phi}^T(t, t_i) \underline{W}_{xx}(t) \underline{\bar{B}}(t, t_i) + \underline{\phi}^T(t, t_i) \underline{W}_{xu}(t)] dt \quad (2-20)$$

and

$$\underline{\bar{B}}(t, t_i) = \int_{t_i}^{t_i} \underline{\phi}(t, \tau) \underline{B}(\tau) d\tau \quad (2-21)$$

Thus the desire to exert control between sample times has generated cross terms in the discrete quadratic cost function. Heuristically, Equation (2-20) can be interpreted as an indication of how coupling between the states and the control inputs can arise in the cost function. The second term on the right side of Equation (2-20) is a function of  $\underline{W}_{xu}$ , which arises from natural coupling between  $\underline{x}$  and  $\underline{u}$  in the continuous-time setting, such as the desire to control a deflection rate of a control surface, yielding a desire to put a quadratic weighting on the derivative of the system state vector  $\underline{x}(t)$ . The first term

on the right side of Equation (2-20) is a function of  $\underline{W}_{xx}$ ; this indicates that a cross coupling in the discrete cost function can be generated by the desire to exert control between the sample times even if no natural coupling exists in the continuous-time system.

The previous discussion motivates the need for cross coupling terms in the discrete quadratic cost function associated with the LQG regulator. Since this cross coupling exists, there is no need to extend Equation (2-8) to include a direct transmission term as this would not modify the Equation (2-16) (see page 81, Reference 12, for a more detailed treatment of cross coupling as a consequence of a direct feedthrough of the control input).

The optimal gain matrix Equations (2-13) and (2-14) can be modified to account for the addition of cross coupling terms between  $\underline{x}$  and  $\underline{u}$  in the following manner:

$$\begin{aligned} \underline{G}_C^*(t_i) = & (\underline{U}(t_i) + \underline{B}_d^T(t_i) \underline{K}_C(t_{i+1}) \underline{B}_d(t_i))^{-1} \\ & \cdot (\underline{B}_d(t_i) \underline{K}_C(t_{i+1}) \underline{\Phi}(t_{i+1}, t_i) + \underline{S}^T(t_i)) \end{aligned} \quad (2-22)$$

where  $\underline{K}_C$  is now defined as the solution to:

$$\begin{aligned} \underline{K}_C(t_i) = & \underline{X}(t_i) + \underline{\Phi}^T(t_{i+1}, t_i) \underline{K}_C(t_{i+1}) \underline{\Phi}(t_{i+1}, t_i) \\ & - (\underline{B}_d^T(t_i) \underline{K}_C(t_{i+1}) \underline{\Phi}(t_{i+1}, t_i) + \underline{S}^T(t_i)) \underline{G}_C^*(t_i) \end{aligned} \quad (2-23)$$

The LQG stochastic regulator described in this section has been shown to possess desirable qualities such as providing control between sample times and allowing full state feedback to be replaced with Kalman filter estimates. However, it suffers from the drawback of displaying type zero characteristics (4:199-201). The desire to compensate for modeling errors, reject constant unmodeled disturbances, and achieve zero steady state tracking error, motivates a design which displays type 1 behavior. Such a controller is the proportional plus integral design developed in Section 2.3.

### 2.3      Synthesis of PI Controllers             via LQG Methods

As stated in the previous section, the desire to obtain a controller which exhibits type 1 characteristics motivates investigation of proportional plus integral forms. In this section the PI controller of classical control theory is derived using modern methods under LQG assumptions. The application of LQG synthesis techniques to the design of PI controllers allows for systematic extension from SISO to MIMO systems (particularly for the proper evaluation of cross-coupling gains in a MIMO PI controller), and therefore, greater flexibility in flight control design problems. The LQG design of PI controllers is further motivated by other important factors such as iterative design capability, ease of off-diagonal weighting

between integral and proportional channels, stability of LQ designs, and robustness enhancement through both LTR and implicit model following techniques. Again, unless stated otherwise the development of this section is taken from Reference 12.

Before embarking on the mathematical derivation of the PI controller, it is in order to discuss some of the motivations for implementing this particular type of controller structure. Consider a controller driven by an error signal, which in turn generates a system control input. It is desirable to structure this controller in such a manner as to maintain control of the state trajectories of the system even in the event that the input to the controller itself is driven to zero (13); e.g., if the tracking error is zero, under a particular set of equilibrium conditions, one still wants the controller to produce the control necessary to keep the system at that desirable equilibrium condition. The PI structure is able to accomplish this task due to the "integral action" which is not inherent in simple regulator schemes (13). A second advantage gained by PI forms over simple regulator structures is the ability to reject constant unmodeled disturbances, thereby improving steady state performance of the system (13). A conclusion that can be drawn from the foregoing discussion is that, while not absolutely necessary for

flight control applications, the PI controller structure can be a significant improvement over simple regulator forms.

Consider a nominal control  $\underline{u}_0$  needed to hold a deterministic time invariant system of the form

$$\underline{x}(t_{i+1}) = \underline{\phi}\underline{x}(t_i) + \underline{B}_d\underline{u}(t_i) \quad (2-24)$$

in an equilibrium condition. The nominal control could represent the control necessary to maintain an aircraft in a specified maneuver or trim condition.

From the above definition of  $\underline{u}_0$ , the nominal state trajectory  $\underline{x}_0$  can be written as

$$\underline{x}_0 = \underline{\phi}\underline{x}_0 + \underline{B}_d\underline{u}_0 \quad (2-25)$$

and a desired set of control variables are defined by

$$\underline{y}_d = \underline{C}\underline{x}_0 + \underline{D}_y\underline{u}_0 \quad (2-26)$$

(Note that the direct feedthrough matrix  $\underline{D}_y$  is explicitly included here. Because the derivation of the PI controller involves more than just a simple LQ design, this term cannot be removed from Equation (2-26) by embedding it in cost function cross terms as was done in the derivation of simple regulator forms.)

In matrix form; Equations (2-25) and (2-26) become

$$\begin{bmatrix} \underline{\Phi} - \underline{I} & \underline{B}_d \\ \underline{C} & \underline{D}_y \end{bmatrix} \begin{bmatrix} \underline{x}_o \\ \underline{u}_o \end{bmatrix} = \begin{bmatrix} \underline{0} \\ \underline{y}_o \end{bmatrix} \quad (2-27)$$

This matrix equation can be used to solve the  $\underline{x}_o$  and  $\underline{u}_o$  by

$$\begin{bmatrix} \underline{x}_o \\ \underline{u}_o \end{bmatrix} = \begin{bmatrix} \underline{\Phi} - \underline{I} & \underline{B}_d \\ \underline{C} & \underline{D}_y \end{bmatrix}^{-1} \begin{bmatrix} \underline{0} \\ \underline{y}_d \end{bmatrix} \quad (2-28)$$

where the augmented matrix inverse can be partitioned as:

$$\begin{bmatrix} \underline{\Phi} - \underline{I} & \underline{B}_d \\ \underline{C} & \underline{D}_y \end{bmatrix}^{-1} = \begin{bmatrix} \underline{\Pi}_{11} & \underline{\Pi}_{12} \\ \underline{\Pi}_{21} & \underline{\Pi}_{22} \end{bmatrix} \quad (2-29)$$

For cases where the matrix on the left side of Equation (2-29) is not square, pseudoinverse techniques may be used to yield a solution in some cases (12:124; 22:142); however, for the purposes of this development it is assumed that the number of controls is equal to the number of controlled outputs and that the matrix in question is in fact invertible, so pseudoinverse forms will not be needed. With the nominal state trajectory and control defined by Equation (2-28), it is now possible to define the following set of perturbation variables:

$$\underline{\delta x}(t_i) = \underline{x}(t_i) - \underline{x}_o = \underline{x}(t_i) - \underline{\Pi}_{12} \underline{y}_d \quad (2-30)$$

$$\underline{\delta u}(t_i) = \underline{u}(t_i) - \underline{u}_0 = \underline{u}(t_i) - \Pi_{22}\underline{y}_d \quad (2-31)$$

and

$$\underline{\delta y}_c(t_i) = \underline{y}_c(t_i) - \underline{y}_d \quad (2-32)$$

As discussed in Section 2.2, it is desired to regulate these perturbation variables to zero; however, it is further desired that this be accomplished with a controller which incorporates integral action into its design. The derivation to follow will develop such a controller based upon pseudorates (13).

The difference in the control perturbation state over,  $\underline{\delta u}$ , one sample time can be expressed, using Equation (2-31), as

$$\underline{\delta u}(t_{i+1}) - \underline{\delta u}(t_i) = (\underline{u}(t_{i+1}) - \underline{u}_0) - (\underline{u}(t_i) - \underline{u}_0) \quad (2-33)$$

Therefore,  $\underline{\delta u}(t_{i+1})$  may be expressed as

$$\underline{\delta u}(t_{i+1}) = \underline{\delta u}(t_i) + (\underline{u}(t_{i+1}) - \underline{u}(t_i)) \quad (2-34)$$

where the second term on the right side of Equation (3-34) can be interpreted as an Euler or tangent line integration (13:68,81) as shown in Equation (2-35).

$$\underline{\delta u}(t_i) = (\underline{u}(t_{i+1}) - \underline{u}(t_i)) \approx \Delta t \dot{\underline{u}}(t_i) \quad (2-35)$$

From Equations (2-34) and (2-35)  $\underline{\delta u}$  may be defined as a new state variable and augmented to Equation (2-24) to form the new state space model:

$$\begin{bmatrix} \underline{\delta x}(t_{i+1}) \\ \underline{\delta u}(t_{i+1}) \end{bmatrix} = \begin{bmatrix} \underline{\Phi} & \underline{B_d} \\ \underline{0} & \underline{I} \end{bmatrix} \begin{bmatrix} \underline{\delta x}(t_i) \\ \underline{\delta u}(t_i) \end{bmatrix} + \begin{bmatrix} \underline{0} \\ \underline{I} \end{bmatrix} \underline{\delta u}(t_i) \quad (2-36)$$

where the pseudo rate  $\underline{\delta u}$  now forms the control input to the augmented system model.

The quadratic cost function which is minimized in order to yield an optimal deterministic control for the system of Equation (2-36) is

$$J = \sum_{i=-1}^N \left\{ \begin{bmatrix} \underline{\delta x}(t_i) \\ \underline{\delta u}(t_i) \\ \underline{\Delta u}(t_i) \end{bmatrix}^T \begin{bmatrix} \underline{X}_{11} & \underline{X}_{12} & \underline{S}_1 \\ \underline{X}_{12}^T & \underline{X}_{22} & \underline{S}_2 \\ \underline{S}_1^T & \underline{S}_2^T & \underline{U} \end{bmatrix} \begin{bmatrix} \underline{\delta x}(t_i) \\ \underline{\delta u}(t_i) \\ \underline{\Delta u}(t_i) \end{bmatrix} \right\} + \frac{1}{2} \begin{bmatrix} \underline{\delta x}(t_{N+1}) \\ \underline{\delta u}(t_{N+1}) \end{bmatrix}^T \begin{bmatrix} \underline{X}_{f11} & \underline{0} \\ \underline{0} & \underline{0} \end{bmatrix} \begin{bmatrix} \underline{\delta x}(t_{N+1}) \\ \underline{\delta u}(t_{N+1}) \end{bmatrix} \quad (2-37)$$

Note that the lower limit on the summation in Equation (2-37) starts at -1 instead of 0. This change in the usual quadratic cost notation is motivated by the need to control the initial condition of the system in order to achieve good initial transient responses through placing a weight on  $\underline{u}(t_{-1})$  (12:142). The  $\underline{X}_{11}$  term in Equation (2-37)

provides a cost weighting on the state trajectory deviation from nominal and  $\underline{X}_{22}$  weights control magnitudes, both of which could have been accomplished by the regulator formulation of the previous section. However, the  $\underline{U}$  term is a weighting on control differences, which under the approximation of Equation (2-35) can be considered a weighting on control rates. The cross terms  $\underline{X}_{12}$ ,  $\underline{S}_1$ , and  $\underline{S}_2$  can arise through natural coupling or through discretization of a continuous cost function as discussed in the simple regulator case of Section 2.2.

Solving for the optimal control function based upon Equation (2-37), and restricting attention to cost functions which allow the terminal time to approach infinity; yields a constant gain feedback control law of the form

$$\underline{\Delta u}(t_i) = -(\underline{G}_{c1}^* \mid \underline{G}_{c2}^*) \begin{bmatrix} \underline{\delta x}(t_i) \\ \underline{\delta u}(t_i) \end{bmatrix} \quad (2-38)$$

where the gains  $\underline{G}_{c1}^*$  and  $\underline{G}_{c2}^*$  can be solved for in the same manner presented in Section 2.2.

Although Equation (2-38) represents an optimal perturbation regulator with a capability to regulate both control magnitudes and control rates, it does not achieve the desired objective of attaining type 1 system response since it lacks integral action. This deficiency will now be addressed.

The desired form of the PI controller based upon Equations (2-35) and (2-38) should be an optimal control signal constructed in terms of the system perturbation states of the following form:

$$\begin{aligned} \underline{\delta u}^*(t_{i+1}) = & \underline{\delta u}^*(t_i) - \underline{K}_x (\underline{\delta x}(t_{i+1}) - \underline{\delta x}(t_i)) \\ & - \underline{K}_z (\underline{C} \underline{\delta x}(t_i) + \underline{D}_y \underline{\delta u}(t_i)) \end{aligned} \quad (2-39)$$

where  $\underline{K}_x$  and  $\underline{K}_z$  are constant gain matrices. The top partition of Equation (2-36) can be written as

$$\underline{\delta x}(t_{i+1}) = \underline{\delta x}(t_i) + (\underline{\Phi} - \underline{I}) \underline{\delta x}(t_i) + \underline{B}_d \underline{\delta u}(t_i) \quad (2-40)$$

Inserting Equation (2-40) into (2-39) and writing in matrix form yields

$$\underline{\delta u}^*(t_{i+1}) - \underline{\delta u}^*(t_i) = -(\underline{K}_x \underline{K}_z) \begin{bmatrix} \underline{\Phi} - \underline{I} & \underline{B}_d \\ \underline{C} & \underline{D}_y \end{bmatrix} \begin{bmatrix} \underline{\delta x}(t_i) \\ \underline{\delta u}(t_i) \end{bmatrix} \quad (2-41)$$

By setting the right sides of Equations (2-39) and (2-41) equal, the gains  $\underline{K}_x$  and  $\underline{K}_z$  may be evaluated as

$$\underline{K}_x = \underline{G}_{c1}^* \underline{\Pi}_{11} + \underline{G}_{c2}^* \underline{\Pi}_{21} \quad (2-42)$$

and

$$\underline{K}_z = \underline{G}_{c1}^* \underline{\Pi}_{12} + \underline{G}_{c2}^* \underline{\Pi}_{22} \quad (2-43)$$

Thus, once  $\underline{G}_c^*$  is established,  $\underline{K}_x$  and  $\underline{K}_z$  may be computed.

Under the assumption that  $y_d$  is piecewise constant and varies slowly enough to allow any system transients to damp out sufficiently between changes, then the PI control law becomes

$$\begin{aligned} \underline{u}^*(t_i) = & \underline{u}^*(t_{i-1}) - \underline{K}_x(\underline{x}(t_i) - \underline{x}(t_{i-1})) \\ & + \underline{K}_z(y_d(t_i) - y_c(t_{i-1})) \quad (2-44) \end{aligned}$$

A diagram of this PI controller form is shown in Figure 2.1 on the next page.

This represents the final form of the pseudorate PI controller derived using LQG methods. This controller achieves type 1 characteristics; therefore, it will be able to track the desired nominal trajectories with zero mean error despite imperfect models or constant unknown disturbances such as steady cross winds.

At the beginning of this section, two assumptions were made which will now be justified. First, the system was assumed to be linear and time invariant. This assumption may seem restrictive. However, one of the motivations of linearizing aircraft equations of motion about a nominal flight condition is to produce a time invariant system model (6) for ease of controller synthesis; therefore, for the purposes of aircraft control system design, this is considered valid. Second, the original system in Equation (2-24) was unrealistically assumed to be deterministic with full state accessibility. However, under the LQG

Fig. 2.1. Position Form PI Control Law Based on Control Differences

assumptions, certainty equivalence may be invoked if only partial, noise-corrupted measurements are available, as in the case of the regulator design of the previous section, and a Kalman filter may be introduced into the loop to provide estimates of the system states.

#### 2.4 Model Following Controllers

Up to this point in the development of the theory to be used in Chapter V, the controllers presented have been intended primarily for the purpose of regulating a set of control variables to zero or some other specified trim condition. Another objective of the final controller to be implemented in this study is the ability for forcing the controlled variables to behave like those of a pre-determined model (7:10-13). In terms of classical control theory, this method can be equated to designing to meet specifications such as damping ratio, peak overshoot, rise time, etc. (4), or in the context of flight control this would include the incorporation of handling qualities (6:490-526) specifically into the design process. A technique which accomplishes this task is aptly referred to as "model following," and can be divided into two distinct categories, both of which will be presented in this section.

Before proceeding with the development of the two forms of model following controllers, the reader is advised to keep in mind that this section is intended as a

conceptual introduction to model following controllers, meant primarily for those who may not be familiar with the basic theory. The CGT type of model following controller implemented in Chapter V is not derived until Section 2.5, in order to allow the reader to become familiar with the general concepts of model following before being exposed to the more detailed and application-oriented form presented in the following section. The material which follows is taken from References 16 and 7 unless stated otherwise.

The first class of model following controllers is known as the implicit model following type. This is due to the fact that, for this class of controllers, the system dynamics of the model are not incorporated explicitly into the on-line controller; rather, the model is embedded into the definition of the cost function and thus affects the manner in which the controller gains are evaluated. In the second class, the model system dynamics are simulated by the controller, with the difference between the modeled output and the system output being incorporated into a cost function. Thus, these controllers are said to exhibit explicit model following characteristics. Implicit model following controllers will be presented first, followed by a derivation of explicit types.

Consider a continuous-time formulation of Equation (2-24):

$$\dot{\underline{x}}(t) = \underline{F}\underline{x}(t) + \underline{B}\underline{u}(t) \quad (2-45)$$

where justification of a deterministic time invariant model for flight control purposes was presented at the end of Section 2.3. Also assume an optimal feedback control law of the following form:

$$\underline{u}^*(t_i) = -\underline{G}_C^*(t_i)\underline{x}(t_i) \quad (2-46)$$

The above simple regulator type control law is being used in order to provide insights into implicit model following; the same concepts could be embedded into a PI formulation as well. Note that  $\underline{u}(t)$  is equal to  $\underline{u}(t_i)$  for  $t_i \leq t < t_{i+1}$  with a zero order hold used for digital-to-analog interfacing. An optimal control function can be achieved based on Equation (2-46) by minimizing the continuous-time cost function

$$J_I = \frac{1}{2} \int_0^{\infty} [\underline{x}^T(t) \underline{X} \underline{x}(t) + \underline{u}^T(t) \underline{U} \underline{u}(t)] dt \quad (2-47)$$

where Equation (2-47) exerts a quadratic weight on control energy and state trajectory deviations from zero. A discrete-time version of Equation (2-47) can be derived based upon the same procedure used to discretize Equation (2-16) (11:203,225). Note that the infinite upper integration limit in Equation (2-47) will allow for constant gain controllers since terminal transients can be neglected.

Now define a set of controlled variables

$$\underline{y}(t) = \underline{C}\underline{x}(t) \quad (2-48)$$

It is desired that the trajectories of these controlled variables track a set of model variables denoted by the differential equation

$$\dot{\underline{y}}_m(t) = \underline{F}_m \underline{y}_m(t) \quad (2-49)$$

where it is required that both  $\underline{y}_m(t)$  and  $\underline{y}(t)$  be p-dimensional vectors.

In order to provide a weighting on controlled variable deviation from the model characteristics described by Equation (2-49), a quadratic cost is established that will penalize  $\underline{y}(t)$  deviations from the desired characteristics of:

$$\dot{\underline{y}}(t) = \underline{F}_m \underline{y}(t) \quad (2-50)$$

Thus, by implicitly incorporating the modeled system into the cost function by placing a quadratic penalty on the difference between the actual  $\dot{\underline{y}}$  and the right side of Equation (2-50), and also adding a cost on the control "energy"  $\frac{1}{2} \sum_{i=1}^r u_i^2(t)$ , the quadratic cost function becomes

$$J_I = \frac{1}{2} \int_0^{\infty} \left\{ \dot{\underline{Y}}(t) - \underline{F}_m \underline{Y}(t) \right\}^T \underline{Y}_I \left( \dot{\underline{Y}}(t) - \underline{F}_m \underline{Y}(t) \right) + \underline{u}^T(t) \underline{U} \underline{u}(t) \right\} dt \quad (2-51)$$

By invoking Equation (2-48), Equation (2-51) becomes

$$J_I = \frac{1}{2} \int_0^{\infty} \left\{ \underline{x}^T(t) \underline{X}_I \underline{x}(t) + 2 \underline{u}^T(t) \underline{S}_I \underline{x}(t) + \underline{u}^T(t) \underline{U}_I \underline{u}(t) \right\} dt \quad (2-52)$$

where

$$\underline{X}_I = (\underline{C}\underline{F} - \underline{F}_m \underline{C})^T \underline{Y}_I (\underline{C}\underline{F} - \underline{F}_m \underline{C}) \quad (2-53)$$

$$\underline{S}_I = \underline{B}^T \underline{C}^T \underline{Y}_I (\underline{C}\underline{F} - \underline{F}_m \underline{C}) \quad (2-54)$$

and

$$\underline{U}_I = \underline{U} + \underline{B}^T \underline{C}^T \underline{Y}_I \underline{C} \underline{B} \quad (2-55)$$

The cross term  $\underline{S}_I$  arises due to the need to track derivatives of the system outputs, i.e. output rates of Equation (2-50). Once the cost function of Equation (2-52) has been defined, an equivalent discrete form may be derived to yield a sample data control law rather than a continuous type (12:74-76). Controllers for this sample data system can be derived via methods presented in either Section 2.2 or Section 2.3 to yield an optimal control function  $\underline{u}^*(t_i)$ .

A second approach to model following design is explicit model following. In order to present this approach, the same basic system of Equation (2-45) will be employed. It is worth noting that although the same model equation is used in the derivation of both the implicit and explicit model following controllers, the  $\underline{F}_m$  is not the same for both cases.

Consider a system modeling the desired characteristics of the plant

$$\dot{\underline{x}}_m = \underline{F}_m \underline{x}_m \quad (2-56)$$

where time arguments have been dropped for notational tractability.

Now define a new state equation based on the augmentation of the plant states and the model states

$$\dot{\underline{x}}' = \frac{d}{dt} \begin{bmatrix} \underline{x} \\ \underline{x}_m \end{bmatrix} = \begin{bmatrix} \underline{F} & \underline{0} \\ \underline{0} & \underline{F}_m \end{bmatrix} \begin{bmatrix} \underline{x} \\ \underline{x}_m \end{bmatrix} + \begin{bmatrix} \underline{B} \\ \underline{0} \end{bmatrix} \underline{u} \quad (2-57)$$

Thus Equation (2-57) may be represented by

$$\dot{\underline{x}}' = \underline{F}' \underline{x}' + \underline{B}' \underline{u} \quad (2-58)$$

The output vector for the augmented system is defined by

$$\underline{y}' = (\underline{y}_c - \underline{y}_m) = \underline{C}\underline{x} - \underline{C}_m \underline{x}_m = [\underline{C} \mid \underline{C}_m] \begin{bmatrix} \underline{x} \\ -\underline{x}_m \end{bmatrix} = \underline{C}' \underline{x}' \quad (2-59)$$

where  $\underline{C}'$  is chosen to accomplish the desired differencing between modeled state variables and plant controlled variables. Therefore, a standard quadratic performance index may be defined by

$$\underline{J}_E = \int_0^{\infty} \frac{1}{2} (\underline{Y}'^T \underline{Y}_E \underline{Y} + \underline{u}^T \underline{R} \underline{u}) dt \quad (2-60)$$

The optimal control input for the augmented system as generated by solving the backward Riccati difference equation associated with Equation (2-60) is

$$\underline{u}^* = -[\underline{G}_{C1}^* \quad \underline{G}_{C2}^*] \underline{x}' \quad (2-61)$$

From Equation (2-61) it can be seen that the optimal control input to the system is comprised of the system states fed back through a gain matrix  $\underline{G}_{C1}^*$ , plus model states fed forward through the set of gains  $\underline{G}_{C2}^*$ . The feedback through  $\underline{G}_{C1}^*$  should provide for tight tracking (7:10-13) which yields a system that is fast enough to follow the responses of the modeled system as commanded through the feedforward controller structure. It can be shown that the feedback compensator is independent of the structure of the explicitly modeled system. Thus, a simple regulator or a PI controller may be designed independently of the explicit model characteristics. As will be shown in the subsequent section, this feedback may be structured in such a manner

as to exploit implicit model following to enhance controller robustness characteristics and explicit model following for handling qualities.

Either of the previously discussed model following techniques would prove to be adequate under the idealized assumptions of perfect models which were uncorrupted by disturbances. However, in actual application each type exhibits certain advantages and disadvantages relative to the other.

Implicit model following bases its control on a weighting of rate deviations, as evidenced by Equation (2-51). Therefore, this type of controller achieves a better tracking of the transient response of the model system than explicit model following controllers do. Also, since the implicit formulation attempts to match system and model pole placement, this method exhibits better rejection of unmodeled zero mean disturbances than explicit types. Specifically, since it affects the feedback path rather than a feedforward path, implicit model following may be used to improve the robustness of the controlled system.

As previously stated, the explicit model following technique must embed a model of the system dynamics within the controller. The impact of this embedded model is twofold. First, a more complex controller is needed since the model states are augmented to the system states. This entails higher computational loading. Second, a time lag

may be introduced into the system, possibly forcing the designer to settle for a suboptimal control law to offset this controller-induced delay. Since the actual difference between the system and model outputs are weighted, no specific pole placement is achieved as in the implicit scheme; thus, the explicit model controller often must maintain higher feedback gains in order to track modeled transient responses. However, this direct comparison of system and model outputs also produce desirable qualities such as improved steady state performance and reduced sensitivity to parameter variations (7:10-13; 16:1-8).

A primary area of importance to be considered when weighing the relative advantages and disadvantages of model following controllers is robustness enhancement (see Chapter IV). The implicit model following controller can have an effect on system robustness since it incorporates a model system into the cost function to be minimized and thereby affects the feedback gains. Therefore, if the form of the implicit model is chosen properly, it can improve the overall robustness of the system (7:10-13). Alternatively, the explicit scheme allows the model to affect only the feedforward path of the control system. As a result of this, the controller based solely upon an explicit model could improve handling qualities; however, it would not be able to improve system robustness characteristics (14). In view of the apparent differences between the objectives

to be achieved by implementing an implicit or explicit controller, it should be emphasized that the implicit and explicit models are not one in the same.

In the past the implicit approach has been more widely used due mainly to its ease of implementation (7:10-13). However, an approach which will be introduced in the following section of this chapter will propose using both implicit and explicit forms in one controller in an attempt to achieve the desirable characteristics of each.

## 2.5 Command Generator Tracker Synthesis Techniques

This section introduces the controller design technique known as command generator tracking (CGT). This formulation requires a system to track commanded inputs with desirable response characteristics, while simultaneously rejecting disturbances. Thus, the CGT controller is capable of forcing the system state variables of interest to maintain desired trajectories (12:151,166). In terms of the language introduced in the previous section, the CGT scheme relies on explicit model following techniques; however, as will be discussed later in this section, implicit model following may also be incorporated into CGT/regulator or CGT/PI designs (16; 7:10-13; 14). The CGT technique is particularly attractive for aircraft flight controller design because it allows handling qualities to be incorporated directly into the design process.

In order to develop the CGT technique, consider the linear time invariant system model

$$\underline{x}(t_{i+1}) = \underline{\phi}\underline{x}(t_i) + \underline{B}_d\underline{u}(t_i) + \underline{E}\underline{x}_n(t_i) + \underline{w}_d(t_i) \quad (2-62)$$

$$\underline{y}(t_i) = \underline{C}\underline{x}(t_i) + \underline{D}_y\underline{u}(t_i) + \underline{E}_y\underline{n}_d(t_i) \quad (2-63)$$

where  $\underline{w}_d(t_i)$  is a zero-mean white Gaussian noise sequence, and  $\underline{n}_d(t_i)$  is a time correlated noise sequence modeled by

$$\underline{n}_d(t_{i+1}) = \underline{\phi}_n\underline{n}_d(t_i) + \underline{B}_{dn}\underline{n}_{cmd}(t_i) + \underline{G}_{dn}\underline{w}_{dn}(t_i) \quad (2-64)$$

It is desired that the output of Equation (2-63) emulate the output of a command generator model

$$\underline{x}_m(t_{i+1}) = \underline{\phi}_m\underline{x}_m(t_i) + \underline{B}_{dm}\underline{u}_m \quad (2-65)$$

$$\underline{y}_m(t_i) = \underline{C}_m\underline{x}_m(t_i) + \underline{D}_m\underline{u}_m \quad (2-66)$$

where  $\underline{y}_m(t_i)$  and  $\underline{y}(t_i)$  must both be of dimension  $p$ . For flight control applications, the input  $\underline{u}_m$  to the command generator model can be considered piecewise constant over a time interval of interest since it is assumed to vary slowly in comparison to the sampling rate of the digital control system.

In order to achieve tracking of the modeled system, the CGT must drive the error

$$\underline{e}(t_i) = \underline{y}_c(t_i) - \underline{y}_m(t_i) \quad (2-67)$$

to zero. In terms of the previously established models, Equation (2-67) can be expressed as

$$\underline{e}(t_i) = (\underline{C} \ \underline{D}_y \ \underline{E}_y) \begin{bmatrix} \underline{x}(t_i) \\ \underline{u}(t_i) \\ \underline{n}_d(t_i) \end{bmatrix} - [\underline{C}_m \ \underline{D}_m] \begin{bmatrix} \underline{x}_m(t_i) \\ \underline{u}_m \end{bmatrix} \quad (2-68)$$

For convenience in construction of the final CGT law, an ideal trajectory can be defined as the plant state trajectory which will drive Equation (2-68) to zero for all time and satisfy

$$\underline{x}_I(t_{i+1}) = \underline{\phi} \underline{x}_I(t_i) + \underline{B}_d \underline{u}_I(t_i) + \underline{E}_x \underline{n}_d(t_i) \quad (2-69)$$

The stated desire to drive the error defined in Equation (2-67) to zero, coupled with the form of Equations (2-68) and (2-69) can be combined with a third condition:

$$\begin{bmatrix} \underline{x}_I(t_i) \\ \underline{u}_I(t_i) \end{bmatrix} = \begin{bmatrix} \underline{A}_{11} & \underline{A}_{12} & \underline{A}_{13} \\ \underline{A}_{21} & \underline{A}_{22} & \underline{A}_{23} \end{bmatrix} \begin{bmatrix} \underline{x}_m(t_i) \\ \underline{u}_m(t_i) \\ \underline{n}_d(t_i) \end{bmatrix} \quad (2-70)$$

Recalling Equation (2-29),

$$\begin{bmatrix} \underline{\phi} - \underline{I} & \underline{B}_d \\ \underline{C} & \underline{D}_y \end{bmatrix}^{-1} = \begin{bmatrix} \underline{\Pi}_{11} & \underline{\Pi}_{12} \\ \underline{\Pi}_{13} & \underline{\Pi}_{14} \end{bmatrix} \quad (2-71)$$

the solution to the CGT problem formulation can be shown (12:155) to be of the form of Equation (2-70) with:

$$\underline{A}_{11} = \underline{\Pi}_{11} \underline{A}_{11} (\underline{\phi}_m - \underline{I}) + \underline{\Pi}_{12} \underline{C}_m \quad (2-72)$$

$$\underline{A}_{12} = \underline{\Pi}_{11} \underline{A}_{11} \underline{B}_{dm} + \underline{\Pi}_{12} \underline{D}_m \quad (2-73)$$

$$\underline{A}_{13} = \underline{\Pi}_{11} \underline{A}_{13} (\underline{\phi}_n - \underline{I}) - \underline{\Pi}_{11} \underline{E}_x - \underline{\Pi}_{12} \underline{E}_y \quad (2-74)$$

$$\underline{A}_{21} = \underline{\Pi}_{21} \underline{A}_{11} (\underline{\phi}_m - \underline{I}) + \underline{\Pi}_{22} \underline{C}_m \quad (2-75)$$

$$\underline{A}_{22} = \underline{\Pi}_{21} \underline{A}_{11} \underline{B}_{dm} + \underline{\Pi}_{22} \underline{D}_m \quad (2-76)$$

$$\underline{A}_{23} = \underline{\Pi}_{21} \underline{A}_{13} (\underline{\phi}_n - \underline{I}) - \underline{\Pi}_{21} \underline{E}_x - \underline{\Pi}_{22} \underline{E}_y \quad (2-77)$$

Upon solving Equations (2-72) through (2-77), the control input can be generated as the lower partition of Equation (2-70):

$$\underline{u}_I(t_i) = \underline{A}_{21} \underline{x}_m(t_i) + \underline{A}_{22} \underline{u}_m(t_i) + \underline{A}_{23} \underline{n}_d(t_i) \quad (2-78)$$

The block diagram of the control law represented by Equation (2-77) is shown in Figure 2.2 on the next page.

As evidenced by Figure 2.2, this formulation of the CGT law is an open loop form; therefore, this controller will not compensate for uncertainties in the system model. The need to compensate for these inevitable uncertainties which arise in flight control applications motivates the construction of a CGT law which incorporates feedback into

Fig. 2.2. Open-Loop Command Generator Tracker

the final design. A second improvement over the simple open loop configuration CGT would be the use of a closed loop PI law, instead of a simple regulator law, thus yielding a command generator tracking/proportional plus integral or (CGT/PI), controller. The advantage of a CGT/PI controller is that it enables the system to achieve type 1 characteristics: (1) it can force the mean steady state error between the actual plant and the command generator model to zero, and (2) it can reject modeled and unmodeled disturbance inputs.

The CGT/PI control law that is used for the purpose this thesis provides type 1 system characteristics and has the desirable quality of being derived via LQG synthesis methods. The final form of this controller can be shown to be of the following form (16:2-15):

$$\begin{aligned}
 \underline{u}(t_i) = & \underline{u}(t_{i-1}) - \underline{K}_x (\underline{x}(t_i) - \underline{x}(t_{i-1})) \\
 & + \underline{K}_z \left\{ \begin{bmatrix} \underline{C}_m & \underline{D}_m \end{bmatrix} \begin{bmatrix} \underline{x}_m(t_{i-1}) \\ \underline{u}_m(t_i) \end{bmatrix} - \begin{bmatrix} \underline{C} & \underline{D}_y \end{bmatrix} \begin{bmatrix} \underline{x}(t_{i-1}) \\ \underline{u}(t_{i-1}) \end{bmatrix} \right\} \\
 & + \underline{K}_{xm} (\underline{x}_m(t_i) - \underline{x}_m(t_{i-1})) \\
 & + \underline{K}_{xu} (\underline{u}_m(t_i) - \underline{u}_m(t_{i-1})) \\
 & + \underline{K}_{xn} (\underline{n}_d(t_i) - \underline{n}_d(t_{i-1}))
 \end{aligned} \tag{2-79}$$

(The use of  $\underline{u}_m$  at  $t_i$  instead of  $t_{i-1}$  accounts for an inconsistency in the definition of the desired state trajectory when a step change to  $\underline{u}$  is applied (12:161-162).) In

terms of Section 2.3 the gains associated with Equation (2-79) are defined as:

$$\underline{K}_x = \underline{G}_1^* \underline{\Pi}_{11} + \underline{G}_2^* \underline{\Pi}_{21} \quad (2-80)$$

$$\underline{K}_z = \underline{G}_1^* \underline{\Pi}_{12} + \underline{G}_2^* \underline{\Pi}_{22} \quad (2-81)$$

$$\underline{K}_{xm} = \underline{K}_x \underline{A}_{11} + \underline{A}_{21} \quad (2-82)$$

$$\underline{K}_{xu} = \underline{K}_x \underline{A}_{12} + \underline{A}_{22} \quad (2-83)$$

$$\underline{K}x_n = \underline{K}_x \underline{A}_{13} + \underline{A}_{23} \quad (2-84)$$

Up to this point the assumption of full state feedback has been allowed, due to certainty equivalence. In order to account for the more accurate physical case of incomplete, noise-corrupted state availability, a Kalman filter can be introduced into the design process. This final innovation will produce what is termed the Command Generator Tracking/Proportional plus Integral/Kalman Filter (CGT/PI/KF) controller. The type of Kalman filter to be employed in the CGT/PI/KF design is a standard steady state, constant-gain filter designed for time invariant system models with stationary noises, ignoring the initial gain transients. For flight control applications a constant-gain filter is acceptable due to the relatively short transient period experienced in relation to the steady state operation of the aircraft.

The Kalman filter will produce a state estimate  $\hat{\underline{x}}(t_i^+)$ ; however, in cases where unmodeled physical delays within the structure of the plant or controller are present, a control law may preferably be established based upon  $\hat{\underline{x}}(t_i^-)$  (12:161). Basing the control input on measurements up to, but not including, the measurement that becomes available at time  $t_i$  can remove computational delay time; however, the resulting control law is less precise than a law based on  $\hat{\underline{x}}(t_i^+)$ . The modeled noise states  $\underline{n}_d(t_i)$  may also be replaced with Kalman filter estimates, but it must be remembered that the plant state estimates and the noise state estimates do not decompose into the independent filters (12:166). Considering the above, the filter model will simply consist of the dynamics model of the plant augmented with the dynamics model of the time correlated noise corruption (16). This augmented filter configuration has a measurement model of the form

$$\underline{z}(t_i) = [\underline{H} \quad \underline{H}_n] \begin{bmatrix} \underline{x}(t_i) \\ \underline{n}_d(t_i) \end{bmatrix} + \underline{v}(t_i) \quad (2-85)$$

where  $\underline{v}(t_i)$  is characterized as a white zero-mean Gaussian noise sequence with a covariance  $\underline{R}$ .

The previous discussion developed the fundamental design equations needed to implement the CGT/PI/KF controller. Although this form of the CGT law is desirable

in that it incorporates a PI controller to achieve type 1 performance characteristics, it has the drawback of being difficult to robustify (see Chapter IV for a discussion of robustness enhancement). Therefore, a slight digression is in order so that a less elaborate form of the CGT law may be presented. This particular form of the CGT controller replaces the PI feedback channel with a simple regulator and may be used if problems arise as a result of applying specific robustness enhancement techniques.

The Command Generator Tracker/Regulator (CGT/R) is developed fully in Reference 12 where it is shown to be of the following form:

$$\begin{aligned} \underline{u}(t_i) = & -\underline{G}_C^* \underline{x}(t_i) + (\underline{A}_{21} + \underline{G}_C^* \underline{A}_{11}) \underline{x}_m(t_i) \\ & + (\underline{A}_{22} + \underline{G}_C^* \underline{A}_{12}) \underline{u}_m(t_i) + (\underline{A}_{23} + \underline{G}_C^* \underline{A}_{13}) \underline{n}_d(t_i) \end{aligned} \quad (2-86)$$

As in the CGT/PI case, the states of the plant and modeled noise corruptions may be estimated by a Kalman filter to yield a CGT/R/KF design. A block diagram of the CGT/PI/KF form is shown in Figure 2.3 on the next page.

The last topic to be discussed in this section relates to the model following techniques introduced in Section 2.4. As previously stated, there exist two sub-categories of model following controllers: implicit and explicit; however, these two forms are not mutually

Fig. 2.3. A Block Diagram of the CGT/PI/KF Controller

exclusive. In this thesis the work developed by Miller (16) will be implemented to derive a controller which exploits both implicit and explicit model following through use of a quadratic cost function of the form

$$J_C = \frac{1}{2} \int_0^{\infty} ((\dot{Y} - \underline{F}_m Y)^T \underline{Y}_I (\dot{Y} - \underline{F}_m Y) + (Y - Y_m)^T \underline{Y}_E (Y - Y_m) + \underline{u}^T \underline{U} \underline{u}) dt \quad (2-87)$$

By using a cost function of the form of Equation (2-87), both the handling qualities and robustness characteristics may be improved by use of explicit and implicit model following, respectively.

Although some standard initialization steps can be used to make a first estimate of  $\underline{Y}_I$  and  $\underline{Y}_E$ , these weightings are usually developed through an iterative trial and error method. Chapter V will provide some insights into this process.

## 2.6 Summary

This chapter has served to generate the basic design tools used in the aircraft controller design of Chapter V. First, the fundamental LQG regulator was introduced and its uses and shortcomings were assessed. Next, the PI controller of classical control theory was developed using

powerful modern LQG methods. Sections 2.4 and 2.5 presented both general model following theory and more specific CGT/PI and CGT/R control forms. Certainty equivalence then allowed definition of CGT/PI/KF and CGT/R/KF laws. The CGT/PI/KF controller design laws will be applied to a fighter aircraft combat mode controller in Chapter V using interactive computer-aided design and evaluation packages (7; 16; 17).

### III. Modeling Considerations for the STOL F-15

#### 3.1 Introduction

This chapter will introduce the models upon which the controller designs of Chapter V are based. Also, some of the unique features of the short takeoff and landing (STOL) F-15 will be discussed. In the interest of clarity and brevity, such data as aerodynamic derivatives and aircraft state models within the flight envelope will not all be presented at this time; instead, these data will be included in Appendix B. The design software used in this thesis (7; 16), will be introduced inasmuch as it is needed to justify specific model development. Those readers who desire a more detailed discussion of the software are directed to References 7 and 16.

The STOL F-15 is a modified version of the F-15 currently being used by the United States Air Force as an air superiority fighter aircraft. The major modifications to the standard F-15 which produce the STOL capability are the introduction of canards, rotating vanes, and two dimensional thrust vectoring nozzles. Of these three modifications, the vanes and thrust nozzles are unconventional control surfaces and bear future explanation. The rotating vanes consist of four louvered panels located on

the upper and lower surfaces of the thrust vectoring attachment located at the rear of the engines. The two dimensional nozzles are located at the rear of the same thrust vectoring assembly. This thesis effort will be limited to a controller design for the "up and away" characteristics of the STOL F-15. Since the rotating vanes do not provide a significant amount of control within the flight envelope being studied, they will be considered closed at all times. Therefore, the vanes are completely eliminated from the control input vector.

The second section of this chapter will introduce some of the basic aerodynamic modeling considerations relevant to the control of the STOL F-15 aircraft. Section 3.3 discusses some of the models other than the basic aircraft model which are motivated by the CGT design method and the computer aided design (CAD) package used to implement this design method. The flight envelope of the STOL F-15 is the topic of Section 3.4. The nominal design point is specified and other points in the flight envelope are discussed as well, with the goal of establishing a "nominal" point to be used for controller designs and several points on the edge of the envelope to be used to evaluate the robustness of these designs.

The final section of this chapter provides a summary of the topics presented and highlights those areas of particular relevance to the subsequent chapters.

### 3.2 Modeling the STOL F-15 Aircraft

This section will discuss the construction of the linearized model used to represent the STOL F-15 aircraft. This presentation will assume that the reader is familiar with atmospheric flight dynamics; those who require a detailed presentation of the fundamental principles of aircraft modeling and flight control are directed to References 6 and 7. The basic aircraft model is derived from the general nonlinear equations of motion which describe the dynamics of the STOL F-15. These equations can be greatly simplified by assuming that: 1) the earth is an inertial plane as opposed to a non-inertial spheroid. This "flat earth" assumption can be considered reasonable at flight conditions which do not exceed Mach 3 (6), which is well below all velocities being considered in this thesis; 2) the atmosphere is at rest; 3) all elastic effects will be considered negligible, yielding a "rigid body" model with no elastic freedom. The rejection of wind buffeting could be incorporated into the controller synthesis methodology (12:151; 14); however, this issue will not be addressed herein. The ability of the controller to reject such disturbances without explicitly modeling them will be assessed, however. The force and moment equations which result from the above simplifying assumptions may be linearized about specific flight conditions, using small disturbance theory (6:154), resulting in a linearized model

for the STOL F-15. By invoking the assumptions concerning aircraft symmetry, absence of gyroscopic effects, and neglecting aerodynamic cross coupling terms (6:161), the lateral and longitudinal modes of the STOL F-15 may be completely decoupled and treated separately for the purposes of controller design. It is this set of decoupled, linearized equations of motion placed in matrix form which will be developed for the longitudinal mode of flight.

The aerodynamic data at various operating points within the flight envelope of the STOL F-15 were provided by McDonnell Aircraft Engineering (McAir). These data consisted of aircraft parameters and longitudinal and lateral non-dimensionalized body axis force coefficients. Also, moments of inertia were provided; however, these were provided in dimensionalized body axis form. In order to convert the data provided by McAir into dimensionalized body axis form, an existing axis conversion program written by Mr. Finley Barfield (3) was modified by Capt. Greg Mandt and Lt. Bruce Clough, and re-named STOLCAT. STOLCAT incorporates the non-dimensionalized body axis force coefficients associated with the canards, two dimensional thrust nozzles, and rotating vanes, along with the conventional force coefficients to produce a set of dimensionalized body axis coefficients. The STOLCAT software also forms both the lateral and longitudinal state space three-degree-of-freedom equations of motion of the following form:

$$\dot{\underline{x}}(t) = \underline{F}\underline{x} + \underline{B}\underline{u}(t) \quad (3-1)$$

where

$\underline{x}$  = aircraft state vector

$\underline{F}$  = aircraft dynamics fundamental matrix

$\underline{B}$  = control derivative matrix

$\underline{u}$  = control vector

At Mach 0.9 at 20,000 feet of altitude, Equation (3-1) is:

$$\begin{bmatrix} \dot{u} \\ \dot{q} \\ \dot{\alpha} \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} -.018 & -20.023 & 27.9 & -32.19 \\ -.23 \times 10^{-3} & -1.999 & 10.81 & 0 \\ -.34 \times 10^{-6} & .9997 & -1.49511 & -7.4 \times 10^{-3} \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} u \\ q \\ \alpha \\ \theta \end{bmatrix} + \begin{bmatrix} 1.5 & -9.9 & 45 \\ 11.7 & -19.69 & 0 \\ -.045 & -.19 & 0 \\ 0 & 0 & 0 \end{bmatrix} \underline{u}(t) \quad (3-1a)$$

A complete FORTRAN program listing of STOLCAT, along with the aerodynamic data for the STOL-F-15, are included in Appendices A and B of this thesis.

In the longitudinal mode the control vector consists of the canard input  $\delta_C$ , the stabilator input  $\delta_S$ , and the throttle input  $\delta_T$ . Although the rotating vanes and thrust vectoring nozzles are available, they are not used in the designs considered in this thesis. The vanes are neglected due to their limited usefulness at the altitude and airspeeds that are being considered. The nozzles are useful for "up-and-away" flight; however, the simultaneous control of thrust and nozzle deflection introduces a severe nonlinearity into the system dynamics which is beyond the scope of this thesis (see Appendix C for a more complete discussion of this nonlinear effect). The longitudinal control vector is shown below:

$$\underline{u}(t) = \begin{bmatrix} \delta_C(t) \\ \delta_S(t) \\ \delta_T(t) \end{bmatrix} \quad (3-2)$$

Although a basic state model representing the aircraft dynamics can be produced by the methods discussed in this section, this model alone will not be sufficient to accomplish the controller designs required of this thesis effort. The use of CGT techniques and the desire to

accomplish performance evaluations of the final designs require that other dynamics models be constructed. The following section will discuss these other dynamics models, which will be used along with the basic aircraft design model to affect the final designs of Chapter V.

### 3.3 Models for CGT Design and Performance Evaluation

Although the previous section developed the linearized decoupled equations of motion for the STOL F-15, these equations alone will not be sufficient to complete the designs required of this thesis. This section will introduce the reader to the models other than the basic aircraft model which will be used in Chapter V. The models presented in this chapter will be somewhat general in nature, thus saving the detailed descriptions of the models particular to the STOL F-15 for Chapter V and Appendix B.

The underlying motivation for the following models is theoretical in nature (see Chapter II); however, their specific form is dictated by the CAD package CGTPIF (7; 16). A discussion of the models from a software user's point of view will be presented at this time in order to give the reader a qualitative understanding of the models as they pertain to the use of CGTPIF. Therefore, the goal of this section is to ground the reader in the uses of the various models presented herein before the actual CGT designs are presented.

Four different models will be described in this section. The first is the design model, followed by the command model or explicit model, the truth model, and finally, the implicit model.

The design model used by CGTPIF is the primary model used in the design process. It is derived from the basic aircraft model Equation (3-1), augmented with noise inputs. The specific form of the design model which is required by CGTPIF is as follows (7):

$$\dot{\underline{x}}(t) = \underline{F}\underline{x}(t) + \underline{B}u(t) + \underline{E}_x \underline{n} + \underline{G}w(t) \quad (3-3)$$

$$\dot{\underline{n}}(t) = \underline{F}_n \underline{n}(t) + \underline{G}_n w_n(t) \quad (3-4)$$

$$\underline{y}(t) = \underline{C}\underline{x}(t) + \underline{D}_y u(t) \quad (3-5)$$

$$\underline{z}(t_i) = \underline{H}\underline{x}(t_i) + \underline{v}(t_i) \quad (3-6)$$

where  $\underline{y}$  represents the controlled outputs and  $\underline{z}$  is the noise-corrupted measurement vector. The  $\underline{n}$  term denotes a time correlated noise disturbance input into the system which is to be rejected by the controller; however, for the purposes of the work accomplished in this thesis, this input will be removed from the system. The noise inputs of the system are characterized by

$$E\{\underline{w}(t)\underline{w}^T(t+\tau)\} = \underline{Q}\delta(\tau) \quad (3-7)$$

$$E\{\underline{w}_n(t)\underline{w}_n^T(t+\tau)\} = \underline{Q}_n\delta(\tau) \quad (3-8)$$

and the measurement noise of the system is described by

$$E\{\underline{v}(t_i)\underline{v}^T(t_j)\} = \underline{R}\delta_{ij} \quad (3-9)$$

The dimensionalities which must be established before entering the design model in the CGTPIF software are

n = number of system states

r = number of system inputs

p = number of system outputs

m = number of system measurements

w = number of independent system noises

The command model is an explicit model (see Sections 2.4 and 2.5) used to describe the desired behavior of the system. Embedded in this model are the specifications that the actual system must meet. Typically for flight control applications this model will be used to command a second order response for the output variables, thus allowing incorporation of specified handling qualities or "feel" of the aircraft as it responds to the pilot's control inputs. A second possible flight control application for the command model would be to command an optimal evasive maneuver for an aircraft operating in a combat situation. The specific form of this model as dictated by CGTPIF is as follows:

$$\dot{\underline{x}}_E(t) = \underline{F}_E \underline{x}_E(t) + \underline{B}_E \underline{u}_E(t) \quad (3-10)$$

$$y_E = C_E x_E(t) + D_E u_E(t) \quad (3-11)$$

where the subscript E denotes Explicit model, and dimensionalities for the command model are

$n_E$  = number of command model states  
 $r_E$  = number of command model inputs  
 $p_E$  = number of command model outputs

CGTPIF further requires that the number of command model states be less than or equal to the number of design model states (software constraint; theoretical extensions are possible), and that the number of system outputs be equal to the number of command model outputs (logical theoretical constraint, since system outputs are supposed to track the command model outputs).

CGTPIF (7; 16) not only provides for the design of Command Generator Tracker/Proportional plus Integral/Kalman Filter (CGT/PI/KF) and Command Generator Tracker/Regulator/Kalman Filter (CGT/R/KF) controllers, but provides for performance analysis of the resulting designs. In order to accomplish this analysis, a linear model must be created which represents, as closely as possible, the actual dynamics of the system. This "truth model" will represent the same system as the design model; however, it will typically be of a higher dimensionality and complexity than the design model since it will include higher order sensor

and actuator dynamics as well as wind buffeting states possibly ignored in the CGT design process. The form of the truth model required by CGTPIF is found in Reference 7 to be:

$$\dot{\underline{x}}_T(t) = \underline{F}_T \underline{x}_T(t) + \underline{B}_T \underline{u}_T(t) + \underline{G}_T \underline{w}_T(t) \quad (3-12)$$

$$\underline{z}_T(t_i) = \underline{H}_T \underline{x}_T(t_i) + \underline{v}_T(t_i) \quad (3-13)$$

$$\underline{x}(t) = \underline{T}_{DT} \underline{x}_T(t) \quad (3-14)$$

$$\underline{n}(t) = \underline{T}_{NT} \underline{x}_T(t) \quad (3-15)$$

with associated noise statistics

$$E\{\underline{w}_T(t) \underline{w}_T^T(t+\tau)\} = \underline{Q}_T \delta(\tau) \quad (3-16)$$

$$E\{\underline{v}_T(t_i) \underline{v}_T^T(t_j)\} = \underline{R}_T \delta_{ij} \quad (3-17)$$

where

$n_T$  = number of truth model states

$r_T$  = number of truth model inputs

$m_T$  = number of truth model measurements

$w_T$  = number of independent noises in the truth model

In Equations (3-14) and (3-15),  $\underline{T}_{DT}$  and  $\underline{T}_{NT}$  are matrices which transform the truth model state and disturbance vectors into vectors corresponding to the design model state and disturbance vectors respectively. In order for CGTPIF to accomplish an analysis of the designed system, obviously  $r_T$  must be equal to  $r$ , and  $m_T$  must equal  $m$ .

The last model to be introduced in this section is the implicit model. This model is not as easily understood on an intuitive level as the previous three (see Section 2.4); however, it may be thought of as a means of providing a pole placement technique to improve the robustness characteristics of the overall control system (see Section 4.2). The implicit model is so named because it is embedded into the process of choosing the weights of an LQ controller and does not, unlike the explicit model, appear explicitly in the final controller implementation. A more detailed discussion of how to design the implicit model to achieve robustness is included in Chapter IV. As with the previous three models, the specific form of the implicit model is a function of CGTPIF requirements (16), and is given by:

$$\dot{Y}_I(t) = \underline{F}_I Y_I(t) \quad (3-18)$$

where

$n_I$  = number of implicit model states

$r_I$  = number of implicit model inputs

$p_I$  = number of implicit model outputs

It cannot be overemphasized that, although implicit and explicit models have the same basic structure and share the same input routine in CGTPIF, they are not the same model, they can and should serve different purposes, and they need not be related in any way.

This section is intended to give the reader a qualitative understanding of the models used in this thesis. It is basically a "bridge" from the theoretical modeling developments in Chapter II to the complete and detailed models presented in Chapter V. Therefore, this section does not stand alone as a complete development of models relevant to this thesis; however, coupled with the developments in Chapters II and V, the reader should transition from a theoretical understanding to a qualitative "feel" to a complete understanding of the specific CGTPIF-oriented models as they pertain to the STOL F-15 aircraft.

#### 3.4 The STOL F-15 Flight Envelope

As stated in the previous section, CGTPIF allows for a performance analysis of completed controllers by use of a truth model to represent the "real world" characteristics of the system being controlled. To be more specific, it allows analysis of the full-state feedback controller and a separate analysis of the Kalman Filter, but it does not provide for analysis of the total controller as a cascade of these two components. Another CAD package called PERFEVAL is available which allows for a performance analysis of a Kalman Filter based CGT/PI controller (17). This software capability is exploited not only to evaluate the controller designs at the nominal design conditions of Mach 0.9 at 20,000 feet altitude, but also to evaluate the

robustness of the controller throughout the combat operation range of the STOL F-15, and to evaluate control system robustness in the face of variations in stability derivatives, surface failures, mismodeled actuator dynamics, etc. See Figure 3.1 for a depiction of the flight conditions being considered in this thesis. The motivation for designing a robust system with the capability to operate over a large portion of the STOL F-15's flight envelope is two-fold. First, a control system which does not require extensive gain scheduling or real time parameter estimation for adjustment to changes in operating conditions greatly reduces the complexity of the control system. This reduction in controller complexity not only reduces the computational loading of the on-board flight computer system, but reduces the physical space requirements and weight requirements of the controller as well. Second, a system which can at least maintain stability in the face of parameter variations could be a first step in a reconfigurable control system (i.e. a robust law to hold the aircraft in the air while reconfiguration is accomplished), capable of greatly enhancing the survivability of the STOL F-15 in the face of combat damage.

In order to construct the truth models used to represent the variations in the dynamics of the STOL F-15 as the aircraft progresses through its flight envelope, it is necessary to: a) vary the entries uniformly in the truth

Fig. 3.1. STOL F-15 Flight Envelope

model which represent the aircraft's dynamics by a set percentage according to what degree the flight condition is to be varied; b) use data, linearized at flight conditions which lie on or close to the boundaries of the flight envelope which the controller is to operate within, to derive new equations of motion; c) inject noise into the truth model states which are likely to be mismodeled or subject to variations; or d) re-derive the aircraft equations to include possible failures such as partial or total loss of actuators. All of these techniques are discussed in Chapter V.

The STOL F-15's flight envelope is depicted in Figure 3.1. The conditions which are used to construct off-design conditions are shown as boxes, while the nominal design condition, which is chosen as representative of the "standard" flight condition for entering into air-to-air combat (22), is depicted as a triangle.

### 3.5 Summary

This chapter has introduced several important concepts related to modeling the STOL F-15 aircraft, with the goal of using these models to construct CGT/PI and CGT/R control laws. In Section 3.2 the basic assumptions made in order to produce time invariant, linearized, decoupled equations of motion are discussed. Section 3.3 introduced the form of the dynamics equations which are motivated by

the CGTPIF (7; 16) CAD package which is used to generate the controllers of Chapter V. Also, a software package called PERFEVAL (17) is introduced in order to analyze the Kalman-filter-based controllers designed using CGTPIF (see Appendix D). The purpose of Section 3.4 was to justify the points in the flight envelope used as variant operating conditions for analyzing the robustness of the control systems generated during the course of this thesis effort. It is important for the reader to realize that this chapter is not intended as a comprehensive explanation of modeling the STOL F-15 aircraft, but rather a transition to provide familiarization with the types of models and terminology which are used extensively in Chapter V.

## IV. Robustness Enhancement Techniques

### 4.1 Introduction

The concepts and methods of robustness enhancement techniques used in this thesis are discussed in this chapter. Two specific types of robustness techniques are addressed. First, implicit model following techniques are presented. Implicit model following controllers were initially presented in Section 3.4, but in this section the implicit model following technique will briefly be re-examined in the light of its impact on closed-loop full-state feedback system robustness. Secondly, the Loop Transfer Recovery (LTR) technique will be developed and shown to provide asymptotic full-state feedback system robustness characteristics to Kalman-filter-based controllers.

### 4.2 Implicit Model Following

The derivation of the implicit model following technique is contained in Section 3.4, so this section will not be oriented towards mathematical rigor. Instead, the objective of this section is to introduce the reader to some of the qualitative aspects of using the implicit model controller as a robustness enhancement technique without mathematical proof.

Recall from Section 3.4 the implicit model following controller is based on an implicit model of the form

$$\dot{\underline{y}}_I(t) = \underline{F}_I \underline{y}_I(t) \quad (4-1)$$

with a cost function constructed by weighting the following difference:

$$\underline{e}(t) = \dot{\underline{y}}(t) - \underline{F}_I \underline{y}(t) \quad (4-2)$$

along with a quadratic penalty on control values, where  $\underline{y}$  is the output vector associated with the plant. Thus the objective is to force the plant to adopt dynamics as described by the implicit model  $\underline{F}_I$  matrix.

The question which needs to be asked is, how should the implicit model be chosen in order to improve the overall robustness characteristics of the system? In the case of the explicit model, which has no effect on robustness, it is apparent that the model should produce outputs which follow a desirable trajectory for the actual plant outputs to emulate. However, by examining Equation (4-2), it can be seen that the implicit model, unlike the explicit model, is used in its complete dynamical form in the cost function definition. Therefore, the state matrix  $\underline{F}_I$  is used along with the output variables of the actual system to define a cost function for developing the feedback control via LQ methods. The  $\underline{F}_I$  matrix can be thought of as embedding the desired characteristic equation properties

of the controlled variables into the definition of the cost function. Therefore, the implicit model provides the ability to carry out classical "pole placement" in a MIMO design using powerful LQ synthesis techniques.

The preceding discussion defines a classical control theory parallel to implicit model following; however, it does not specifically address the robustness issue. The pole placement concept can be exploited to this end. Consider an aircraft controller design based on a reduced-order model of a system, with order reduction carried out by ignoring actuator dynamics considered to be beyond the bandwidth of the controller. Using LQ synthesis techniques, a regulator or PI controller (see Sections 2.2 and 2.3) can be designed based upon this reduced order model. If, upon completion of the controller design, it is found that the desired bandwidth constraints are violated, the unmodeled actuator dynamics may be excited, resulting in system instability; i.e. the controller is not "robust" in the face of unmodeled higher order dynamics. The inclusion of an implicit model in the cost function used to derive the previously discussed controller provides the designer with a means to place a quadratic penalty on the deviation of Equation (4-2) from zero, thus penalizing deviations of the output variables from behavior which is dictated by the characteristic equation defined by  $\underline{F}_I$  in Equation (4-2). Therefore,  $\underline{F}_I$  may be chosen to "place" the poles of the

controller, providing a means to reduce the system bandwidth and robustify the controller against ignored higher order dynamics. In terms of the classical root locus, the designer should place the desired poles of the system far enough from the unmodeled poles that "unexpected" movement of these unmodeled poles will have the least possible effect on the stability of the overall system (14). It has also been shown that if the eigenvectors of the desired system model are nearly orthogonal, the robustness characteristics of the closed system are improved (14).

#### 4.3 Loop Transfer Recovery

Recall that by invoking certainty equivalence, the LQ controller design can be carried out under the assumption of full state availability. Then, once the final design is complete, the full state feedback may be replaced with a Kalman filter. Intrinsic to the LQ full-state feedback controllers are certain guaranteed minimal stability robustness properties at design conditions (13; 22). Further, as discussed in the previous section, robustness of the full state system to unmodeled plant dynamics can be accomplished using implicit modeling techniques. However, this overall robustness achieved in the full state design is found to be degraded when the Kalman filter is incorporated into the controller (5; 22). In this section a method known as Loop Transfer Recovery (LTR) will be

introduced, which is able to accomplish asymptotic recovery of the full state robustness characteristics. Unless otherwise stated, the following development is taken from Reference 14; however, for a more detailed discussion the reader is directed to References 5, 9, and 22.

The LTR method is a means of "tuning" the Kalman filter used to provide state estimates in order to improve the robustness characteristics of the overall closed loop system. The LTR technique cannot improve the robustness of the controller beyond that of the full state feedback system; however, it can provide robustness up to and asymptotically including that of the original system. The objective of the LTR technique is to tune the Kalman filter in such a manner that the return difference function (9; 22) of the filter-based controller becomes asymptotically equal to the return difference function of the full-state-feedback-system. Recall the dynamical system equation

$$\dot{\underline{x}}(t) = \underline{F}\underline{x}(t) + \underline{B}\underline{u}(t) + \underline{G}\underline{w}(t) \quad (4-3)$$

For a continuous-time, minimum phase system the LTR tuning is based on the following equation:

$$\underline{Q}_{LTR}(q) = \underline{Q}_0 + q^2 \underline{B} \underline{V} \underline{B}^T \quad (4-4)$$

where  $\underline{Q}_0$  is the strength of the dynamics noise in the filter before LTR tuning is applied, and  $\underline{V}$  is any positive definite matrix (commonly chosen to be the identity

matrix  $\underline{I}$ ). The robustness of the LTR-tuned filter/controller approaches that of the full-state-feedback-system as the scalar  $q$  approaches infinity. The physical interpretation of Equation (4-4) is a process of injecting noise into the input channels of the system, i.e. additional white noise is added to the system model at the same points of entry as used by the control inputs  $\underline{u}(t)$ .

The discrete-time formulation of the LTR technique is an extension of the continuous-time case made by any one of the following methods: 1) completing the entire controller design in the continuous-time domain, including the LTR tuning, and discretizing the resulting design; 2) performing the LTR tuning on the continuous-time system, obtaining the equivalent discrete time system model, and proceeding to apply LQG design techniques to the discrete time system; or 3) obtaining the discrete-time model of the system, carry out the LQG design, and then inject white noise into the entry points of  $\underline{u}(t)$ . The white noise which is injected into the system can be replaced by a time correlated noise if robustness enhancement is required over a particular frequency range (9); however, this technique will not be pursued in this thesis. Also, it has been shown that a dual LTR tuning technique exists that recovers the full-state-feedback robustness characteristics of the system by adjusting the weighting matrices of the LQ regulator (21).

However, for the purposes of this thesis, attention will be limited to the technique introduced in Reference 22.

Although the LTR tuning has been shown to provide more enhanced robustness as the scalar  $q$  is increased, it also allows more noise to be passed through the system. This results in degraded performance at design conditions as compared to the non-LTR tuned controller. Therefore, engineering judgment must be used to determine the proper  $q$  which provides the desired balance between system robustness and controller performance at design conditions.

#### 4.4 Summary

In this chapter, two robustness enhancement techniques were introduced. First, implicit model following was presented. This scheme was shown to provide robustness improvement in the face of unmodeled system dynamics by allowing the designer to invoke pole placement, system bandwidth rolloff, and eigenvector orthogonalization techniques directly in an LQG-synthesized controller. Secondly, the LTR technique was shown to be a tuning method which allows the full state robustness characteristics to be recovered asymptotically when a filter is introduced into the loop to provide state estimates.

The preceding development is meant to provide engineering insight, not detailed mathematics. The reader who

desires a more detailed treatment of the robustness enhancement techniques which are applicable to LQG designs is directed to References 5, 9, 13, 16, 21, and 22.

## V. Experimental Methods and Results

### 5.1 Introduction

An analysis of the design work accomplished in the course of this thesis effort, along with a presentation of the results obtained, will be the topic of this chapter. The next four sections of this chapter derive the models for the longitudinal mode dynamics of the STOL F-15 (see Chapter III), followed by a section on pitch pointing controller design. Section 5.7 will present the methods used to test control system robustness, both with and without a Kalman filter embedded in the control system. Finally, Section 5.8 summarizes the preceding sections.

The reader is assumed to have read Chapters III and IV, and at least "scanned" Chapter II (especially Sections 2.3-2.5) before embarking on this chapter. This preparation is necessary since much of the material discussed in these previous chapters will be referenced in this chapter without further explanation.

### 5.2 Detailed Portrayal of Design Model

As discussed in Chapter III, the linearized longitudinal equations of motion for the STOL F-15 are of the following form:

$$\dot{\underline{x}}(t) = \underline{F}\underline{x}(t) + \underline{B}u(t) \quad (5-1)$$

where the state vector  $\underline{x}(t)$  consists of velocity  $u(t)$ , pitch rate  $q(t)$ , angle of attack  $\alpha(t)$ , and pitch angle  $\theta(t)$ . Thus Equation (5-1) becomes

$$\begin{bmatrix} \dot{u}(t) \\ \dot{q}(t) \\ \dot{\alpha}(t) \\ \dot{\theta}(t) \end{bmatrix} = \begin{bmatrix} F_{11} & F_{12} & F_{13} & F_{14} \\ F_{21} & F_{22} & F_{23} & F_{24} \\ F_{31} & F_{32} & F_{33} & F_{34} \\ F_{41} & F_{42} & F_{43} & F_{44} \end{bmatrix} \begin{bmatrix} u(t) \\ q(t) \\ \alpha(t) \\ \theta(t) \end{bmatrix} + \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ B_{21} & B_{22} & B_{23} \\ B_{31} & B_{32} & B_{33} \\ B_{41} & B_{42} & B_{43} \end{bmatrix} \begin{bmatrix} \delta_C(t) \\ \delta_S(t) \\ \delta_T(t) \end{bmatrix} \quad (5-2)$$

where  $\delta_C$ ,  $\delta_S$ , and  $\delta_T$  are the inputs which drive the canard, stabilator, and throttle, respectively. The numerical value of the coefficients in Equation (5-1) for a STOL F-15 at a velocity of mach 0.9 and an altitude of 20,000 feet are computed by STOLCAT using aerodynamic data provided by McAir to be

$$\begin{bmatrix} \dot{u}(t) \\ \dot{q}(t) \\ \dot{\alpha}(t) \\ \dot{\theta}(t) \end{bmatrix} = \begin{bmatrix} -0.18 & -20 & 27.9 & -32.19 \\ -.23 \times 10^{-3} & -1.99 & 10.81 & 0 \\ -.35 \times 10^{-6} & .999 & -1.45 & -.73 \times 10^{-3} \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} u(t) \\ q(t) \\ \alpha(t) \\ \theta(t) \end{bmatrix} + \begin{bmatrix} 1.43 & -9.96 & 45 \\ 11.72 & -19.96 & 0 \\ -.045 & -.19 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \delta_C(t) \\ \delta_S(t) \\ \delta_T(t) \end{bmatrix} \quad (5-3)$$

For numerical values of the F and B matrices in Equation (5-1) at flight conditions other than that of Equation (5-3), see Appendix B.

For reasons which will be discussed in Section 5.4, the output variables were chosen to be

$$\underline{Y}(t) = \underline{C}\underline{x}(t) = \begin{bmatrix} \gamma(t) \\ \theta(t) \\ q(t) \end{bmatrix} \quad (5-4)$$

where  $\gamma(t)$  is flight path angle. Using the approximation

$$\theta \approx \alpha + \gamma \quad (5-5)$$

the C matrix of Equation (5-4) is determined to be

$$\underline{C} = \begin{bmatrix} 0 & 0 & -1 & 1 \\ 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \end{bmatrix} \quad (5-6)$$

(Note that during the course of the research conducted in conjunction with this thesis, a nonlinear dynamical equation of motion for the STOL F-15 was derived which allowed for the simultaneous control of both thrust and nozzle deflection. See Appendix D for a discussion of this model and problems encountered in its implementation for controller design.)

All controllers presented in this chapter are designed based on this four-state design model in order to keep controller complexity to a minimum. However, for performance analysis of these designs, a more complex "truth model" will need to be derived. This truth model is the subject of the following section in this chapter.

### 5.3 Truth Model Specification

The truth model derivation begins with the four-state aircraft model presented in Section 5.2. In order to provide a more complete aircraft model, actuator dynamics states were augmented to these original system states. The dynamics associated with the canard and the stabilator actuators were given by McAir to be of the following form:

$$\frac{\delta_S(s)}{e_{\delta_S}(s)} = \frac{\delta_C(s)}{e_{\delta_C}(s)} = \frac{\delta(s)}{e_{\delta}(s)} = \frac{30.62(272.7)^2}{(s+30.62)(s^2+277.2s+74474)} \quad (5-7)$$

where  $e_{\delta}$  is the commanded value of  $\delta$ . The associated state space representation is:

$$\begin{bmatrix} \dot{\delta}(t) \\ \ddot{\delta}(t) \\ \dddot{\delta}(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ -2.3 \times 10^{-6} & -8.3 \times 10^{-5} & -307.8 \end{bmatrix} \begin{bmatrix} \delta(t) \\ \dot{\delta}(t) \\ \ddot{\delta}(t) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 2.3 \times 10^6 \end{bmatrix} e_{\delta}(t) \quad (5-8)$$

Also, first order actuator dynamics for the throttle dynamics were approximated using the first order lag response

$$\frac{\delta_T(t)}{e_{\delta_T}(s)} = \frac{20}{s + 20} \quad (5-9)$$

or, in state space form

$$\dot{\delta}_T(t) = \frac{-1}{20} \delta_T(t) + 20 e_{\delta_T}(t) \quad (5-10)$$

With these states augmented to the original system states, the resulting truth model is shown in Figure 5.1 on the next page.

In order to accomplish a reduction in the complexity of this truth model to lessen the computational burden with minimal impact on truth model adequacy, the third order actuator dynamics associated with the canard and stabilator are replaced with second order approximations (10) of the form:

$$\frac{\delta_S(s)}{e_{\delta_S}(s)} = \frac{\delta_C(s)}{e_{\delta_C}(s)} = \frac{\delta(s)}{e_{\delta}(s)} = \frac{8356.2}{s^2 + 303.52s + 8356.2} \quad (5-11)$$

When represented in state space form Equation (5-11) becomes:

$$\begin{bmatrix} \dot{\delta}(t) \\ \ddot{\delta}(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -8356.2 & -303.52 \end{bmatrix} \begin{bmatrix} \delta(t) \\ \dot{\delta}(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 8356.2 \end{bmatrix} e_{\delta}(t) \quad (5-12)$$

As can be seen from Figure 5.2, this is an accurate approximation over the bandwidth of interest in the system. The

$$\begin{bmatrix} \dot{u} \\ \dot{q} \\ \dot{\alpha} \\ \dot{\theta} \\ \dot{\delta}_C \\ \dot{\delta}_C \\ \dot{\delta}_C \\ \dot{\delta}_S \\ \dot{\delta}_S \\ \dot{\delta}_S \\ \dot{\delta}_T \end{bmatrix} = \begin{bmatrix} F_{11} & F_{12} & F_{13} & F_{14} & B_{11} & 0 & 0 & 0 & B_{12} & 0 & B_{13} \\ F_{21} & F_{22} & F_{23} & F_{24} & B_{21} & 0 & 0 & 0 & B_{22} & 0 & B_{23} \\ F_{31} & F_{32} & F_{33} & F_{34} & B_{31} & 0 & 0 & 0 & B_{32} & 0 & B_{33} \\ F_{41} & F_{42} & F_{43} & F_{44} & B_{41} & 0 & 0 & 0 & B_{42} & 0 & B_{43} \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -2.3 \times 10^6 & -8.3 \times 10^5 & -307.8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -2.3 \times 10^6 & -8.3 \times 10^5 & -307.8 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -20 \end{bmatrix} \begin{bmatrix} u \\ q \\ \alpha \\ \theta \\ \delta_C \\ \delta_C \\ \delta_C \\ \delta_S \\ \delta_S \\ \delta_S \\ \delta_T \end{bmatrix} + \begin{bmatrix} e_{\delta_C} \\ e_{\delta_S} \\ e_{\delta_T} \end{bmatrix}$$

Fig. 5.1. Eleven-State Truth Model

# FREQ. RES. FOR 3RD AND 2ND ORDER ACTUATORS

Fig. 5.2. Comparison of Second Order and Third Order Actuator Frequency Responses

truth model which results from the reduced order actuator dynamics approximation is shown in Figure 5.3 on the next page.

In order to yield the same output variables as those found in Equation (5-4), the  $\underline{C}$  matrix for the truth model of Figure 5.3 is

$$\underline{C} = \begin{bmatrix} 0 & 0 & -1 & 1 & | & 0 & 0 & | & 0 & 0 & | & 0 \\ 0 & 0 & 0 & 1 & | & 0 & 0 & | & 0 & 0 & | & 0 \\ 0 & 1 & 0 & 0 & | & 0 & 0 & | & 0 & 0 & | & 0 \end{bmatrix} \quad (5-13)$$

Also, the  $\underline{T}_{NT}$  matrix discussed in Chapter III, which is used to relate the states of the truth model to the states of the design model for CGTPIF performance evaluation (7; 16), is

$$\underline{T}_{NT} = \begin{bmatrix} 1 & 0 & 0 & 0 & | & 0 & 0 & | & 0 & 0 & | & 0 \\ 0 & 1 & 0 & 0 & | & 0 & 0 & | & 0 & 0 & | & 0 \\ 0 & 0 & 1 & 0 & | & 0 & 0 & | & 0 & 0 & | & 0 \\ 0 & 0 & 0 & 1 & | & 0 & 0 & | & 0 & 0 & | & 0 \end{bmatrix} \quad (5-14)$$

As discussed in Chapter III, it will be this truth model which is used to represent the "real world" characteristics of the STOL F-15 in both linear and nonlinear computer analysis of the pitch pointing controller presented in Section 5.7 of this chapter. The nonlinearities of the latter analysis have to do with magnitude and rate saturations of the actuators.

$$\begin{bmatrix} u \\ q \\ \alpha \\ \theta \\ \delta_C \\ \delta_C \\ \delta_S \\ \delta_S \\ \delta_T \end{bmatrix} = \begin{bmatrix} F_{11} & F_{12} & F_{13} & F_{14} & B_{11} & 0 & B_{21} & 0 & B_{13} \\ F_{21} & F_{22} & F_{23} & F_{24} & B_{21} & 0 & B_{22} & 0 & B_{23} \\ F_{31} & F_{32} & F_{33} & F_{34} & B_{31} & 0 & B_{23} & 0 & B_{33} \\ F_{41} & F_{42} & F_{43} & F_{44} & B_{41} & 0 & B_{24} & 0 & B_{34} \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -2356.2 & -303.5 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -2356.2 & -303.5 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -20 \end{bmatrix} \begin{bmatrix} e_{\delta_C} \\ e_{\delta_S} \\ e_{\delta_T} \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 8356.2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 8356.2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} e_{\delta_C} \\ e_{\delta_S} \\ e_{\delta_T} \end{bmatrix}$$

Fig. 5.3. Nine-State Truth Model

This ends the derivation of the aerodynamic data based aircraft models. It is important for the reader to realize that the design and truth models are functions of the airframe configuration of the STOL F-15 and the actuator dynamics associated with the servos which drive its control surfaces; however, the models which are presented in the following two sections are not directly tied to the physical properties of the aircraft itself. Instead, they are derived by the designer based on the desired performance characteristics of the controller.

#### 5.4 Explicit Model Derivation

Unlike the two previously presented models, the explicit model is not based on provided aerodynamic data. Instead, it is completely determined by the control system designer based, in this case, on the desired aircraft handling qualities. The first step which was taken in deriving this model was to define the system outputs needed in order to accomplish the pitch pointing maneuver. Since pitch pointing entails decoupling pitch angle and flight path, these two angles are obvious candidates for output variables. As stated in Chapter III, the design software (7; 16) requires that the number of outputs be equal to the number of inputs, which in this case is 3. Therefore, one output variable remains to be chosen. Based on previous work in this area, the third output variable was chosen to

be pitch rate, since this has been shown to increase controller stability (7; 16).

The next step that was taken after the output variables were defined, was to establish the desired trajectories for these variables to follow. It was to this end that the explicit model was designed. For a pitch pointing maneuver, the flight path requires no states in the explicit model, since this output variable is to be commanded to zero for all time. This can be simply accomplished by "zeroing out" the row in the explicit model output matrix which corresponds to the flight path variable. The desired trajectory for the pitch angle was expressed using a second order explicit model dynamics of the following form:

$$\begin{bmatrix} \dot{x}(t) \\ \ddot{x}(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_N & -\zeta\omega_N \end{bmatrix} \begin{bmatrix} x(t) \\ \dot{x}(t) \end{bmatrix} + \begin{bmatrix} 0 \\ \omega_N \end{bmatrix} K\delta_{CMD}(t) \quad (5-15)$$

where  $\delta_{CMD}(t)$  is the commanded pitch angle step change (0.035 radians or 2 degrees for the designs analyzed in this study) and  $x(t)$  is the desirable model-achieved pitch angle. Note that  $\zeta$  and  $\omega_N$  were chosen to be 0.5 and 3 rad/sec respectively, in order to provide the type damping and natural frequency response desired by fighter aircraft pilots (8). In the first attempt to form the explicit model for pitch rate, a first order model was used; however, when excited by a step input (the only type of

command input available in CGTPIF), the first order model commanded a non-zero steady state output to the system. Although the dynamics of the system eventually drove the actual pitch rate to an extremely small value over the 6 second time period examined for the aircraft responses in the combat mode of operation, they were not exactly zero. This small steady state error in pitch rate resulted in a constant rate of change in the control surface deflection and overall long-term system instability. In an attempt to alleviate this problem, a second order model was introduced for pitch rate. This model is of the same basic form as Equation (5-15). However, instead of taking  $\dot{x}$  as the ideal trajectory to be tracked,  $x$  was used since this value would have a steady state value of exactly zero. Through an iterative process, the entry in the  $\underline{B}$  matrix which corresponds to the input to the pitch rate model was adjusted to achieve the best tracking of the command model outputs by the outputs of the actual system. It was observed that usually the best results were obtained when the value of the entry in the  $\underline{B}$  matrix for a second order system was about 10-15 percent larger than the systems natural damping frequency,  $\omega_N$ . The damping of the second order pitch rate model was chosen to be 0.707 in order to minimize settling time and, as discovered by empirical observation, the natural frequency which achieved best overall tracking by the actual system was the same as the natural frequency of

the pitch angle model, i.e., 3 rad/sec. The final form of the explicit model based on the above derivation is:

$$\begin{bmatrix} \dot{x}_1(t) \\ \ddot{x}_1(t) \\ \dot{x}_2(t) \\ \ddot{x}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -9 & -4.32 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -9 & -3 \end{bmatrix} \begin{bmatrix} x_1(t) \\ \dot{x}_1(t) \\ x_2(t) \\ \dot{x}_2(t) \end{bmatrix} + \begin{bmatrix} 0 \\ 10 \\ 0 \\ 9 \end{bmatrix} \delta_{\text{CMD}}(t) \quad (5-16)$$

with the model output matrix

$$y_m(t) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ \dot{x}_1 \\ x_2 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} \gamma_{\text{IDEAL}}(t) \\ \theta_{\text{IDEAL}}(t) \\ q_{\text{IDEAL}}(t) \end{bmatrix} \quad (5-17)$$

Figure 5.4, next page, is a plot of the time histories of these "ideal" responses.

### 5.5 Implicit Model Derivation

Like the explicit model discussed in the previous section, the implicit model is also completely dictated by the designer based on the specifications to be met by the final control design. For the purposes of the design accomplished in this thesis effort, the implicit model was constructed to provide system robustness in the face of unmodeled high frequency dynamics of the system. This robustness enhancement is basically a high frequency "roll off" effect (see Section 4.2).

Fig. 5.4. Ideal Explicit Model Aircraft Responses

At the points in the envelope which were considered in this study (see Section 3.4), aside from Mach 0.3 at 20,000 ft as will be discussed shortly, the implicit model was used as a means to embed bandwidth reduction into the LQ design process. For all of these flight conditions, the implicit model used was of the following form:

$$\dot{\underline{x}}_I(t) = \begin{bmatrix} -0.1 & 0 & 0 \\ 0 & -0.1 & 0 \\ 0 & 0 & -0.1 \end{bmatrix} \underline{x}_I(t) \quad (5-18)$$

As the magnitudes of the negative numbers along the diagonal of Equation (5-18) were reduced, the bandwidth of the system was also reduced; however, if these entries were made too small, the pitch rate displayed an oscillation. This problem can be explained by recalling that the implicit model can be thought of as a pole placement technique. Thus as the entries in the  $\underline{F}_I$  matrix become smaller they drive the poles of the system towards the imaginary axis in the s-plane and induce neutral system stability.

Based on the above, it can be seen that the implicit model is desired to reduce the system bandwidth. While the ability to limit the bandwidth showed to be a useful application for the implicit model, it also showed some limited ability; in fact, to speed up the system when working at the mach 0.3 @ 20,000 ft. flight condition.

However, this "band-extension" characteristic showed only flight change in the overall response of the system at this point in the envelope. This is attributed to the fact that, while the implicit model can artificially slow down (i.e. reduce the bandwidth) of a fast system, it cannot speed up what would otherwise be a sluggish system without lowering the weights on the control amplitudes and rates. At best, it was found that the implicit model was useful to "push" the slower flight condition to the limits of its maximum bandwidth capability. This was accomplished by entering large negative entries along the major diagonal of the  $\underline{F}_I$  matrix in the implicit model. For the controller designed at Mach 0.3 at 20,000 ft, it was found that the implicit model which achieved the fastest settling to an initial condition (where an initial condition is defined as steady state value for the state lasting from time equal to  $-\infty$  to  $0^-$  and set to zero at time  $0^+$ ) without introducing instability was

$$\dot{\underline{x}}_I(t) = \begin{bmatrix} -24 & 0 & 0 \\ 0 & -24 & 0 \\ 0 & 0 & -24 \end{bmatrix} \underline{x}_I(t) \quad (5-19)$$

where the off-diagonal terms are zero for reasons discussed in Section 4.2.

Based on the preceding discussion, it can be stated that the implicit model is extremely useful as a bandwidth reduction technique and somewhat useful as a "band extension" technique. However, for both applications care must be taken to limit the magnitude of the entries in the  $\underline{F}$  matrix so as not to induce system instability.

#### 5.6 Pitch Pointing Controller Design

Through use of the advanced control surface architecture used on the STOL F-15 (see Chapter III), certain maneuvers are possible which cannot be performed on a conventional F-15 aircraft. In the longitudinal mode, these maneuvers consist of pitch pointing and vertical translation, the former of which will be the subject of the control design presented in this section. The characteristic which separates these "enhanced" maneuvers from conventional maneuvers is the ability to use control surfaces to produce lift while driving moments to zero, i.e., to generate "direct lift" (15:69, 72).

Pitch pointing consists of pointing the aircraft's nose up or down while maintaining a fixed flight path. This maneuver is especially useful for air-to-air gunnery since gun sight errors may be easily nulled without changing the trajectory of the aircraft. In terms of angles used to describe the longitudinal orientation of the aircraft, pitch pointing consists of commanding the flight

path angle to zero while simultaneously commanding a desired pitch angle. A second maneuver which exploits the direct lift capabilities of the STOL F-15 is vertical translation; however, this mode of flight is not addressed in this thesis.

The first step which was taken in the design of the pitch pointing controller was to determine the weighting matrices to be used in the definition of the cost function used to derive the PI control law. The initial attempt used the strategy that the inverse of the square of the maximum variation allowable in a particular variable being weighted would serve as the weighting on that variable (12). This approximation is considered reasonable due to the fact that, if all variables weighted in this manner reach maximum allowable values simultaneously, they will contribute equivalent amounts to the cost, so that the controller will expend equal amounts of effort on all channels. This weighting scheme is depicted in Equations (5-20) to (5-22) below:

$$\underline{w}_{u_m}(i,i) = \frac{1}{[\text{Maximum Control Surface Deflection}]^2} \quad (5-20)$$

for the weights on the control magnitudes, as in Equation (2-19),

$$\underline{w}_{u_R}(i,i) = \frac{1}{[\text{Maximum Control Surface Rate}]^2} \quad (5-21)$$

for the weights on the control rates, as in Equation (2-37), and

$$\underline{W}_y(i,i) = \frac{1}{[\text{Maximum Allowable Deviation in Output}]^2} \quad (5-22)$$

for the weights on the output magnitudes, as in Equation (2-18), where  $\underline{W}(i,i)$  is the  $(i,i)$  element of the diagonal weighting matrix. From the information provided by McAir (20), the following rate and deflection limits were obtained for the canard and stabilator:

$$\text{Canard Position Limits} = -35^\circ; +15^\circ \quad (5-23)$$

$$\text{Canard Rate Limit} = 23^\circ/\text{sec} \quad (5-24)$$

$$\text{Stabilator Position Limits} = -29^\circ; +15^\circ \quad (5-25)$$

$$\text{Stabilator Rate Limit} = 46^\circ/\text{sec} \quad (5-26)$$

Based on Equations (5-23) to (5-26), the magnitude weightings for the input vector  $\underline{u}(t)$ , (recall that the entries of  $\underline{u}$  consist of  $\delta_C$ ,  $\delta_S$ , and  $\delta_T$ ) were determined to be

$$\underline{W}_{u_m} = \begin{bmatrix} 14.59 & 0 & 0 \\ 0 & 14.59 & 0 \\ 0 & 0 & 14.59 \end{bmatrix} \quad (5-27)$$

in Equation (2-19), and the rate weights were determined to be

$$\underline{W}_{u_R} = \begin{bmatrix} 6.21 & 0 & 0 \\ 0 & 1.55 & 0 \\ 0 & 0 & 1.55 \end{bmatrix} \quad (5-28)$$

For instance, the 1,1 element of  $\underline{W}_{u_m}$  is  $1/[\text{.262 rad}]^2$  since this was the smaller of the upper and lower limits. Note that in Equations (5-27) and (5-28), the value for weightings on throttle input magnitude and throttle input rate were assumed to be approximately the same value as the other weightings in these weighting matrices. This assumption was made based simply on the lack of any quantitative information of the physical limitations of the throttle response for the STOL F-15 and bears further investigation.

In order to make a "first cut" derivation of the weighting matrix on the system outputs,  $y$ , a 10.47 milliradian (0.6 degrees) pitch point was considered. Assuming deviation of no more than 10 percent yielded a maximum allowable deviation of 1.047 milliradians (0.06 degrees). In order to obtain a weighting on flight path, it was assumed that the flight path should be allowed ten times less deviation than pitch angle, i.e., 0.1047 milliradians (0.006 degrees). Similarly, the pitch rate weight was initially set based on the weighting of pitch angle (since these states are linearly related through a derivative). Based on these assumptions the output variable weighting matrix

becomes (recalling that the output variables are  $\gamma$ ,  $\theta$ , and  $q$ , respectively):

$$\underline{W}_y = \begin{bmatrix} 9.16 \times 10^6 & 0 & 0 \\ 0 & 9.16 \times 10^5 & 0 \\ 0 & 0 & 9.16 \times 10^5 \end{bmatrix} \quad (5-29)$$

The initial designs were based on the above weighting matrices and the explicit model of Equation (5-16). These controllers showed responses almost identical to those of the ideal responses when tested using a truth model which was identical to the design model for evaluation purposes; see Figure 5.5 next page (compare the upper portion of Figure 5.5 to the ideal response of Figure 5.4). (Admittedly, this is a questionable practice at best. However, for the purposes of this study all designs were initially tested against the four-state design model for the purpose of establishing the desired characteristics to embed in the explicit model to achieve desirable handling qualities. By no means were these evaluations meant to yield any stability information about the system.) However, when the truth model varied from the design model, the system designed on the basis of the above weightings was unstable, both with and without implicit model following (see the lower portion of Figure 5.5). The desire to achieve tight control over the output variables, as evidenced by Equation (5-29), proved

to have disastrous effects on system robustness. It was found that the solution to this problem was to abandon the "inverse-maximum deviation-squared" solution to the weighting matrices in favor of a more intuitive approach.

The observation was made that, if the values of the weighting matrix determinants differed from one another appreciably (by approximately more than two orders of magnitude), the controller designed based on these weights would be unstable in the face of linear second-order actuator dynamics in the truth model. Therefore, the diagonal entries of all three weighting matrices were set equal to 0.1 and then were adjusted iteratively until the desired responses were achieved with a nine-state truth model. The thought progression for determining the weights which needed to be changed was as follows:

1. Starting from the "equal-weighting" condition of 0.1 along the diagonal of each weighting matrix, the system response was analyzed against the four-state truth model (again, this was not a test of system robustness, but rather, a test of acceptable system response in general). If a rate or position limit was violated in the actuators, then the weight associated with that rate or magnitude was increased in order to exert more restraint over that variable, and thus reduce its expenditure of control energy. Interestingly, the weights associated with the output variables needed no adjustment at this time since the

Fig. 5.6. Aircraft Response Without (Upper) and With (Lower) Actuators/Well Chosen Weighting Matrices; 1 = flight path; 2 = pitch angle; 3 = pitch rate

trajectories of the output variables were close to the ideal case depicted in Figure 5.4 (compare Figure 5.4 and the upper section of Figure 5.6).

2. At this point, the controller was tested against the 9-state linear truth model of Figure 5.3 and the system was found to be unstable. In order to stabilize the system, the weights on the output variables were reduced to allow for less "tight control" of these variables under "off-design" conditions. It was found that this procedure did indeed stabilize the system in the face of actuator dynamics; see the lower portion of Figure 5.6. It was also observed that the pitch rate channel was by far the best indicator of system stability; i.e., when the system was near instability, oscillations would appear in the pitch rate. Some degree of this oscillatory behavior continued on the pitch rate channel despite attempts to change the weighting of the controlled variables; see the lower section of Figure 5.7 on the next page.

3. Finally, the implicit model of Equation (5-18) was introduced into the controller design. The weightings on magnitude and rate variations were determined using the same type of procedure used in step 1 to be:

$$\underline{W}_{u_{mI}} = \begin{bmatrix} .02 & 0 & 0 \\ 0 & .02 & 0 \\ 0 & 0 & .02 \end{bmatrix} \quad (5-30)$$

$$\underline{W}_{u_{RI}} = \begin{bmatrix} .002 & 0 & 0 \\ 0 & .002 & 0 \\ 0 & 0 & .002 \end{bmatrix} \quad (5-31)$$

respectively. The criterion for acceptable performance was reduced ringing in the pitch rate channel when tested against the nine-state truth model, as shown in the upper section of Figure 5.7.

Based on steps 1 and 2, the weighting matrices of Equations (5-27) to (5-29) were adjusted to be (see Figure 5.6 and the upper portion of Figure 5.7 for the aircraft responses using these weightings):

$$\underline{W}_{u_m} = \begin{bmatrix} .02 & 0 & 0 \\ 0 & .02 & 0 \\ 0 & 0 & .02 \end{bmatrix} \quad (5-32)$$

$$\underline{W}_{u_R} = \begin{bmatrix} .008 & 0 & 0 \\ 0 & .008 & 0 \\ 0 & 0 & .008 \end{bmatrix} \quad (5-33)$$

and

$$\underline{W}_y = \begin{bmatrix} .08 & 0 & 0 \\ 0 & .05 & 0 \\ 0 & 0 & .01 \end{bmatrix} \quad (5-34)$$

The above process was carried out for the four flight conditions presented in Section 3.4, and stabilized controllers were obtained at these flight conditions when tested against a nine-state truth model. All designs were achieved using the same weighting matrices, explicit model, and implicit model (except for the implicit model used at Mach 0.3 at 20,000 ft., as discussed in Section 5.5). Therefore, the results presented for this thesis will be those at the "nominal" flight condition of Mach 0.9 at 20,000 ft., since this is representative of both the results and design methodologies used at all flight conditions.

The final controller was designed based on the previously described weighting matrices and the implicit and explicit models of Equations (5-16) and (5-18). The resulting gain matrices (see Section 3.5, especially Equation (2-79)) were generated using CGTPIF (7; 16):

$$\underline{K}_x = \begin{bmatrix} .4319 \times 10^{-5} & 5.643 & -235.8 & .3534 \\ .7038 \times 10^{-5} & .4257 & -140.5 & .1653 \\ .806 & .3077 & -23.84 & .4177 \times 10^{-1} \end{bmatrix} \quad (5-35)$$

$$\underline{K}_z = \begin{bmatrix} 9.066 & -8.844 & 5.981 \\ 5.325 & -5.665 & 3.234 \\ 1.375 & -.7268 & .979 \end{bmatrix} \quad (5-36)$$

$$\underline{K}_{xm} = \begin{bmatrix} -1.219 & 11.54 & -244.9 & -6.25 \\ -.2815 & 4.048 & -145.4 & -3.715 \\ -.7221 \times 10^{-1} & 1.352 & -24.52 & -.6312 \end{bmatrix} \quad (5-37)$$

$$\underline{K}_{xu} = \begin{bmatrix} .6428 \\ -.1105 \\ .8416 \times 10^{-2} \end{bmatrix} \quad (5-38)$$

The responses to a 0.035 radian (2 degrees) pitch point command for a controller based on Equation (2-79) with the gain matrices of Equations (5-35) to (5-38) are shown for both a four-state truth model, Figure 5.8, and a nine-state truth model, Figure 5.9, on the following pages. Note that in both cases the aircraft responses are close to those of Figure 5.4. However, for the nine-state case a slight ringing occurs in the pitch rate channel; this is due to the instabilities introduced by including the actuators in the truth model while maintaining a four-state design model. This ringing appears pronounced due to the common scaling of the output variables. However, this is actually an acceptable response as evidenced by the pitch angle and flight path channels; i.e., the pitch

a. Aircraft responses; b. Control deflections

Fig. 5.9. Aircraft Response with Actuators  
a. Aircraft responses; b. Control deflections

pointing maneuver itself is accomplished well despite the time lags introduced by the actuator dynamics.

Once the full-state controller design was complete, a constant-gain Kalman filter was separately designed to replace the assumption of full state availability with state estimates based upon noise-corrupted partial state availability. The measurements were modeled to be of the following form:

$$\underline{z}(t_i) = \underline{H}\underline{x}(t_i) + \underline{v}(t_i) \quad (5-39)$$

where

$$\underline{H} = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \quad (5-40)$$

The covariance of the measurement noise,  $\underline{v}(t_i)$ , was taken from Reference 7 to be

$$\underline{R} = \begin{bmatrix} .476 \times 10^{-5} & 0 & 0 \\ 0 & .122 \times 10^{-4} & 0 \\ 0 & 0 & .322 \times 10^{-4} \end{bmatrix} \quad (5-41)$$

In this development, a term  $\underline{G}w(t)$  was added to the dynamics state equation, with  $w(t)$  being zero-mean white Gaussian noise, independent of  $\underline{v}(t_i)$ , and of strength  $Q$  where

$$\underline{G} = \begin{bmatrix} 0 \\ 1 \\ 1 \\ 0 \end{bmatrix} ; \quad Q = .001 \quad (5.42)$$

This form of  $\underline{G}w(t)$  is motivated as a "first cut" at introducing the effects of wind buffeting on the aircraft (8). Using CGTPIF and PERFEVAL (7; 16; 17), the Kalman filter gain matrix was determined to be

$$K = \begin{bmatrix} -1.213 & .1626 & .4552 \times 10^{-1} \\ .203 & .2704 & .1635 \\ .1173 & .2032 & .1024 \\ .69 \times 10^{-1} & 4579 \times 10^{-1} & .3001 \times 10^{-1} \end{bmatrix} \quad (5-43)$$

(for a more detailed discussion of basic Kalman Filtering theory the reader is directed to Appendix E and Reference 11). The pitch pointing maneuver with the Kalman filter in the loop is shown in Figure 5.10 on the next page. In order to account for unmodeled time lags in the system, the controller was also tested using the suboptimal control law based on  $\hat{\underline{x}}(t_i^-)$ . This form of the control law bases the control input to the system on the Kalman filter's best estimate of the system states before the actual measurement is incorporated; this allows  $\underline{u}(t_i)$  to be computed before time  $t_i$  to remove computational delay time of

Fig. 5.10. Aircraft Response with Actuators, Position Limits, and Kalman Filter in the Loop

a. Aircraft responses; b. Control deflections

computing  $\hat{\underline{x}}(t_i^+)$  and then the control  $\underline{u}(t_i)$  based on this state estimate. This response is shown in Figure 5.11. Note that the responses both with and without the time delay in the system are essentially the same. Therefore, the impact of using this suboptimal control law is minimal. Also it is apparent that the Kalman filter does not degrade the ability of the controller to achieve the pitch pointing maneuver within a 3.5 second time interval.

The pitch pointing controller design presented in this section has been shown to display desirable characteristics when tested against a nine-state truth model, both with and without a Kalman filter embedded in the control law. It will be these system responses which will serve as a baseline for the robustness analysis discussed in the following section.

### 5.7 Robustness Analysis

The pitch pointing controller presented in the previous section was shown to be stable when evaluated against a nine-state truth model. In this section the controller evaluation will be extended using software generated specifically to include parameter variation and nonlinear effects such as control surface rate and position limits (see Appendix C). Before presenting the results of this robustness analysis, it is in order to state that the parameter variation technique which is employed in this

Fig. 5.11. Aircraft Response with Actuators, Position Limits, and Kalman Filter with the Loop/Control Based on  $\hat{\underline{x}}(t_i)$   
 a. Aircraft responses; b. Control deflections

study is a somewhat limited tool for establishing system robustness. A more precise analytical method (5) would include structured singular value analysis to provide complete information about the system's robustness characteristics; however, this approach is beyond the scope of this thesis. The plotted data corresponding this robustness analysis are contained in Appendix F of this thesis. Also, it should be noted that, for the majority of the robustness analyses presented in this section, actuator rate limits are not included. This is due to the fact that severe instabilities were induced by limiting the rates to those specified in the previous section. However, at the time of this writing, there exists conflicting information about the actual rate limitations of these surfaces. In an attempt to make a "worst case" analysis, the lowest rate limits available are used for the robustness analysis conducted in this thesis.

The first nonlinear effect which was introduced into the system was a "sign swapping" routine to account for a problem which was identified with the linear model (1; 20) (see Appendix C for a discussion of the nonlinear analysis program ODEF15). The problem which existed was that, as the control surfaces passed through zero angle of attack relative to the aircraft, the sign of the coefficient in the B matrix which corresponded to the drag induced by the control surface failed to change sign. Effectively, this

corresponded to a system which could increase thrust by increasing the deflection of the control surfaces. Of course this is a completely unrealistic situation, so the sign swapping routine is included in all of the following analyses without further discussion. Note however that, since velocity is not specifically controlled in this design, airspeed is not held constant in steady state. Therefore, throttle deflection may actually drop in a maneuver which requires an increase in thrust in order to maintain airspeed (however, this drop is not due to the linear analysis problem of experiencing "negative drag" since the sign swapping routine was being employed while this problem was identified). This phenomenon is not a problem over the six-second period determined to be essentially the longest period that the pilot would fly "hands-off" in the flight envelope considered in this study, since the airspeed drops less than 1 percent over this time period. In fact it is common practice to eliminate velocity completely from the dynamical equations of motion using a short period approximation (6), thereby completely ignoring the controller impact on velocity.

The correct way to address this problem is obviously to place a quadratic weight on velocity and exploit the properties of the PI control structure (see Chapter II) to assure constant steady state airspeed. However, due to the limitations of the software (7), in order to augment

velocity to the system outputs, an independent control must be augmented to the input vector. An attempt was made to introduce a new control input by incorporating the thrust vectoring nozzles; however, nonlinearities associated with this problem were severe and the approach was abandoned (see Appendix D for a derivation of this nonlinear model).

Another attempt to provide control of velocity was made by introducing velocity into the existing output vector. First pitch rate control was removed and replaced with velocity control. This approach robbed the system of a significant amount of its robustness characteristics. In fact, without controlling pitch rate the system could not even be stabilized against in the face of second-order actuator dynamics, thus validating the original assumption that pitch rate control would enhance system robustness. The second approach attempted to drive the linear combination of velocity and flight path angle to zero. This resulted in a system which could drive the combination to zero; however, both velocity and flight path angle displayed steady state error (as expected).

Since throttle was available as a system input, two ad-hoc techniques were derived to demonstrate that the throttle input could be used to maintain airspeed if needed in a four-input/four-output system. First an absolute value function was placed on the control input to the throttle:

$$e'_{\delta_T}(t) = \left| e_{\delta_T}(t) \right| \quad (5-44)$$

and  $e'_{\delta_T}(t)$  then replaced  $e_{\delta_T}(t)$  in Equation (5-9). This approach maintained airspeed for a two-degree pitch pointing maneuver; however, it was not practical for varying commanded pitch angles. In order to address this problem, the following form of throttle control was implemented:

$$e''_{\delta_T}(t) = -0.2 e_{\delta_C}(t) \quad (5-45)$$

while the throttle command was made a linear function of stabilator deflection. The system responses using these ad-hoc techniques are shown in Figures F.1 and F.2 in Appendix F.

The first check of system robustness was to evaluate how well the system could withstand variations in the  $\underline{F}$  matrix of Equation (2-4). In order to establish this, all entries were varied by a specific amount in the following form:

$$\underline{\dot{x}}(t) = (\underline{F} + \underline{\Delta F})\underline{x}(t) + \underline{B}u(t) \quad (5-46)$$

The system was found to be able to display acceptable response with the variation  $\underline{\Delta F}$  being up to 100 percent of the matrix  $\underline{F}$ . This insensitivity to variation in  $\underline{F}$  is logical since the original aircraft is unstable at this flight condition, thereby requiring that the controller

suppress the actual dynamics of the system. Plots of 10 percent, 25 percent, 100 percent, and 200 percent increase in  $\underline{F}$  in Appendix F (F.3 to F.6) show the trend of reduction in direct lift capability, creating flight path angle/pitch angle coupling as  $\underline{\Delta F}$  increases. Also note that at 200 percent variation in  $\underline{F}$ , Figure F.6, the pitch rate channel is shown to be the leading indicator of system instability.

Another attempt to create a realistic change in aircraft characteristics was accomplished by failing the canard. This was a "free-floating" failure in which the canard was fixed at zero angle of attack in relation to the relative velocity of the aircraft. This failure resulted in coupling between flight path and pitch angle, which is to be expected since a failure of the canard removes all direct lift capabilities. See Figure F.7 for the full-state feedback aircraft response in the face of a full canard failure. In this plot it is shown that stability is maintained with the canard failure; however, the ability to achieve direct-lift is lost, therefore the pitch pointing maneuver can not be accomplished.

In order to address a common problem known as windup, which can affect the robustness of PI type controllers, an anti-windup compensator was added to the system. Readers who desire a derivation of the anti-windup compensator presented in this study are directed to Reference 16. Windup occurs when a PI controller encounters

saturation limit. While the proportional channel will react immediately to compensate for the large errors which occur as a saturation is encountered, the integral channel will build up to a large control output. This buildup will continue until a sign change occurs in the input to the integral channel, even after the error in the system has been driven back to a small value. This "out of phase" compensation to saturations can induce system oscillation and instability. The anti-windup compensator reduces the effect of this phenomenon by placing limits on the value of the command inputs to the control surfaces of the aircraft. This precludes sending control signals which can cause these surfaces to be driven into saturation, thereby eliminating the possibility of inducing windup in the system. In some cases it was found that anti-windup compensation, when used without imposing saturation limits on the control surfaces in the truth model, could cause instability because it limited the control available to the system. However, for most cases the anti-windup compensator showed improved response. Comparing Figure F.8 to Figure 5.9 shows that the anti-windup compensator has reduced the oscillation in the pitch rate channel for the full-state feedback system with actuator limits. Figures F.9 and F.10 show the aircraft responses with a Kalman filter in the loop and with a Kalman filter with control based on  $\hat{x}(t_i^-)$ , respectively. Notice that these responses are identical to Figures 5.10 and 5.11,

indicating that for these controllers the saturation limits are never reached for a two-degree pitch pointing maneuver.

The sensors used on the STOL F-15 can be modeled using second-order dynamics (20). However, since these measurement dynamics were not included in the truth model, the measurement noise was increased as a "first cut" at evaluating the systems robustness in the face of unmodeled sensor dynamics and other uncertainties. Figure F.11 in Appendix F shows the effect of increasing the measurement noise to a level 40 times higher than that given in Equation (5-41) in the truth model without changing the measurement noise level used to design the Kalman filter. While the system maintained stability with this increased measurement noise, it can be seen from Figure F.11 that this condition causes increased workload on the control surfaces. An attempt was made to limit this overworking of the control surfaces by using anti-windup control; however, as evidenced in Figures F.12 and F.13, this did not remove the flutter in the canard and stabilator.

At this point the LTR tuning technique was introduced in an attempt to enhance system robustness with a Kalman filter in the loop (see Section 4.3). Despite exhaustive attempts to apply this technique, it was found that for all but extremely small values of  $q$  in Equation (4-4), the result was system instability. The system was finally stabilized with a  $q$  value of .00316. The analysis technique used in

this thesis is severely limited in its regard to quantify the increase in system robustness using the LTR technique. First of all, just how much of the full state robustness was lost by introduction of a Kalman filter? If the original Kalman filter-based controller was already near the robustness levels of the full state system, the application of an LTR technique might be a waste of time. On the other hand, if serious robustness degradation has been introduced by the loss of full state availability, there is no way to measure how much has been gained in the way of system robustness with the LTR technique, i.e., when is the point of diminishing returns reached as  $q$  is increased further and further? Without the ability to apply structured singular value analysis, the LTR technique generated more questions than answers. However, attempts were made to analyze the impact of applying the LTR technique despite these shortcomings in the analytical approach available for this research.

In order to establish a standard by which to judge the LTR-tuned controller, white Gaussian noise was injected into the pitch rate and angle of attack channels in the truth model without changing the original controller design, in order to produce visible instability in the system. This process noise was made large enough ( $Q = .08$ ) to have a marked impact on the system, as shown in Figure F.14. Once this "high-noise" baseline was established, the LTR

tuning technique was applied to the control system in an effort to identify any improvement (i.e. less oscillatory behavior) in the face of high noise injection in the truth model. From the response of the system with LTR tuning, Figure F.15 in Appendix F, it can be seen that some reduction in oscillatory behavior of the system is achieved. However, this result is in no way intended to provide conclusive information of the application of the LTR technique; to the contrary, it would be less than technically correct to draw any conclusions from the application of LTR tuning on the basis of this admittedly limited analysis of the technique.

As a final attempt to try a tuning approach to increase the system robustness with the Kalman filter in the loop, an ad-hoc method was attempted based on the following:

$$\underline{Q}(q) = \underline{Q}_0 + q^2 \underline{C}^T \underline{C} \quad (5-47)$$

where all the variables are the same as those presented in Section 4.3 for LTR tuning except for  $\underline{C}$  which is the output matrix of Equation (2-8). Based on the observation that pitch rate is the most sensitive channel to parameter variation, the " $\underline{C}$ -tuned" system was tested using variations in the  $\underline{B}$  matrix of Equation (2-4). The stability derivatives  $M_{\delta_C}$  and  $M_{\delta_S}$  were independently varied, both with and without  $\underline{C}$ -tuning. The results shown in Table 5.1

TABLE 5.1  
EFFECT OF C-TUNING FILTER

	With C Tuning		Without C Tuning	
	$M_{\delta_C}$	$M_{\delta_S}$	$M_{\delta_C}$	$M_{\delta_S}$
Percent Increase in Stability Derivative	16%	16%	7%	10%
Percent Decrease in Stability Derivative	100%	40%	100%	7%

indicate that a substantial increase in system robustness is achieved. Plotted responses of the C-tuned system are given in Appendix F, Figures F.16 through F.23. In Figure F.16 the full-state feedback system response with actuators is shown. It can be seen from this figure that the pitch rate channel exhibits no oscillation, as compared to Figures 5.9 and F.8, indicating increased system stability. However, the settling time is increased from 4.5 seconds to over 6 seconds. This type of tradeoff between robustness and response characteristics is indicative of LTR tuning scheme's characteristics (22). In Figure F.17 the aircraft response is shown with rate limits included in the truth model. Without C-tuning, imposing rate limits on the actuators drove the system into instability even in the full-state feedback system without actuators; however, when C-tuning was employed, the system was stable with not

only rate limits but with actuators, position limits, a Kalman filter in the loop, and a time lag simultaneously introduced in the truth model as well (see Figure F.17). While stability is maintained, an effective steady-state error is incurred over the 6-second time period, as shown in the figure. Comparing Figure F.18 to Figure F.6 shows that, with C-tuning the system is stabilized in the face of a 200 percent additive increase in the F matrix (as compared to 100 percent for the non-C-tuned system of Figure F.5). Figure F.19 shows the C-tuned system response in the face of a 40-fold increase in measurement noise in the truth model. Comparing this response to that of Figures F.11, F.12, and F.13 shows that the control surface flutter is suppressed in the C-tuned system. The aircraft responses for variations in the B matrix stability derivatives,  $M_{\delta_C}$  and  $M_{\delta_S}$  (see Table 5.1) are shown in Figures F.19 through F.23. It should be noted that the C-tuning technique is not being presented as a theoretically correct method to regain system robustness for a CGT/PI/KF controller. Quite the contrary, this method is presented simply as an ad-hoc method which happens to have provided excellent results. To make any statements about this method for general application would require a complete mathematical proof validating that the return difference functions (at some specified loop breaking point of physical significance) for the controller both with and

without the Kalman filter in the loop asymptotically become equal as  $q$  is increased in Equation (5-47). However, time did not allow a full investigation of the validity of this approach. Appendix G provides a preliminary explanation for the results obtained using  $\underline{C}$ -tuning and some comments on the application of LTR tuning for loop breaking at points other than the point at which the input enters the system.

#### 5.8 Summary

This section has presented the pitch pointing controller designed as a part of this thesis effort. The thought process used to arrive at the models and weighting matrices was introduced along with their final form. The robustness of the final controller was analyzed in the face of parameter variations, control surface saturations, canard failure, and highly noise-corrupted measurements. Also, LTR tuning was investigated as a means to recover the robustness of the system lost by introducing a Kalman filter into the controller to provide state estimates. Finally, an ad-hoc method for tuning the filter was introduced along with the encouraging results obtained using this method.

## VI. Conclusions and Recommendations

### 6.1 Introduction

This section is intended to tie together the ideas and design approaches presented in the course of this thesis, at a more general and qualitative level than previously used. This is not a collection of unrelated ideas, but rather, an "overall view" of the research conducted in the course of preparing this document. Hopefully, the reader will be able to obtain an understanding of the nature of the design methodologies which have culminated in the controllers presented herein and the implications of these approaches for future flight control designs.

### 6.2 Conclusions

The most important result which has been demonstrated in research conducted in the writing of this thesis is the complete viability of the CGT/PI/KF design method for MIMO advanced fighter aircraft controller design. Not only was this approach shown to provide a systematic and intuitive design approach, but it was also shown to result in a controller which easily embedded pilot handling qualities and overall system robustness directly into the design process. Implicit model following was used as a method to limit the system bandwidth to guard against

exciting ignored higher-order dynamics and inducing instability. This allowed us to design a system based on a relatively low-order model (four states) which displayed excellent robustness characteristics in the face of unmodeled actuator dynamics, control surface rate and position limits, actuator failures, and extreme variations in both the F and B matrices of the system. Explicit modeling was shown to be an effective means to embed handling qualities into the design process with a small increase in overall controller complexity. Finally, the nature of the iterative design process associated with the LQG-based PI structure allowed for useful insights to be developed readily within the design iterations themselves in order to achieve final specifications.

Another result which is worth including in this discussion is the questions which were raised pertaining to the LTR tuning of a CGT/PI/KF controller structure. While not rigorously proven by any means, the analysis of the LTR approach seemed to indicate that, in this particular case, the implementation of a CGT/PI/KF controller may not be consistent with the application of the original Doyle and Stein method of recovering loop transmission characteristics with the loop broken at the input to the system. A complete analysis of the frequency domain characteristics for the loop broken at various points in the system is appropriate to establish the applicability of the LTR method.

At the onset of this thesis effort, many goals were set to be accomplished. Of these initial goals, most were met or addressed at least to a limited degree. However, even in light of the work accomplished, the tremendous capability of the CGT/PI/KF design method was not fully exploited in the course of this research and bears further investigation.

### 6.3 Recommendations for Further Study

Although some valuable ground has been gained in the course of this thesis work, much more remains to be accomplished in the design and analysis of a CGT/PI/KF flight controller for the STOL F-15. The major areas which need to be addressed are presented in this section. This is not an "all inclusive" list of the possible ramifications of this thesis. However, it is a list of "possibilities" which warrant being addressed in the future.

1. One of the major drawbacks to the controller designs which were able to be accomplished in this research was the lack of integrated software. In order to use the CGT/PI/KF design method to its fullest extent, interactive software must be designed which allows the designer the flexibility not only to achieve the basic design, but also to test the design using actuator and sensor noise, time lags, Kalman filters in the loop, servo saturations and other designer-specified nonlinearities, and LTR tuning

simply by specifying a scalar  $q$  value and where the controller loop is to be broken. Also, as will be discussed below, the ability to accomplish structured singular value analysis and frequency domain analysis is a "must" for the proposed software as a means to establish the relative robustness of controllers in a direct manner. This type of integrated software package, were it available, would allow the designer the flexibility to design a system iteratively while testing it against increasingly accurate portrayals of the "real World" environment in which it is to function. Therefore, it is proposed that this type of CAD package either be designed or purchased for further studies in this area.

2. A problem which arose in the course of this thesis was the simultaneous control of both velocity and thrust vectoring nozzles. As shown in Appendix E, this results in a harshly nonlinear system which could not be adequately controlled using the linear constant-gain approaches adopted in this thesis and parallel efforts (1:20). Either a practical linearization should be applied to this system so that linear techniques may be implemented, or, possibly, more advanced techniques could be applied to this problem using parameter estimation or extended Kalman filtering techniques.

3. For further studies in the control of the STOL F-15, the controller designs should be tested in the face

of wind gusts modeled as outputs of a linear time invariant system driven by white Gaussian noise. Additional states to represent turbulence should be incorporated into the truth model and also, perhaps, in the filter/controller in an attempt to test controller robustness in turbulence.

4. A logical progression from the work accomplished in this thesis would be to extend the control designs to multiple longitudinal maneuvers and to investigate lateral mode controllers as well. A "single controller" approach could be analyzed in an attempt to eliminate the need to adjust controllers to a specific maneuver while at a fixed flight condition. This could produce a control system which is able to perform several maneuvers and relieves the pilot from "switching modes" in order to achieve different maneuvers.

5. An extremely useful tool to analyze the final controllers based on the above suggestions would be to derive dynamical equations of motion for the STOL F-15 which included asymmetrical surface failures. This would allow the impact of mode coupling on the system robustness to be evaluated in a maneuver such as a coordinated turn.

6. An interesting application of the CGT/PI/KF controller could be to attempt a more complicated "maneuver." For instance, instead of a coordinated turn or a pitch pointing, an entire evasive maneuver or automatic

mid-air collision avoidance scenario could be implemented using the aircraft's radar as a system measurement.

7. Last, but certainly not least, it is strongly suggested that for any further application of a CGT/PI/KF controller synthesis, the applicability of LTR tuning be rigorously verified and coupled with the use of structured singular value analysis and frequency domain analysis in order to gain more insight into the entire robustness issue.

## Appendix A: STOLCAT Program Listing

### Introduction

The following computer code listing is the STOLCAT program used to convert the aerodynamic data provided by McDonnell Air Co. into lateral and longitudinal state space three-degree-of-freedom equations of motion (see Section 3.2). It is written in FORTRAN V and is hosted on a Control Data Corporation Cyber mainframe computer. This program is completely interactive and provides prompts to specify the required input and the units for that input. It should be noted that no means is provided to store entered data in a permanent file structure. Therefore, care should be exercised to avoid making errors when entering data to avoid having to re-enter the program to enter all data from the beginning.

## Appendix C: ODEF15

In order to analyze the CGT/PI/KF controller designs used in the course of this thesis, ODEF15 was written. ODEF15 is written in FORTRAN V and is hosted on the CDC Cyber mainframe computer. It is derived from expanding an analysis package known as ODEACT written by Maj W. Miller (16). The software is completely interactive, providing the user with prompts for each input. Also, a file structure is available which allows the user both to read and to write data to local files. The code is specific to the STOL F-15 only in the actuator dynamics and rate/position limits, which are "hardwired" into the software. However, by eliminating the entries of the actuator dynamics and saturation limits from the external subroutine FSTOL, any CGT/PI/KF-controlled system could be analyzed. Files can be formed for Kalman filter-based systems as well as full state feedback systems. The user must declare the library routines IMSL and Ode (International Mathematical and Statistical Library, and Ordinary Differential Equations solver) before running ODEF15 as these libraries are referenced in the main program. For the Kalman filter-based systems, the user is asked how many iterations are desired for the Monte Carlo analysis. It

is advised that the user limit the number of iterations to 7 or less to avoid long computational times (10 run averages can take in excess of 10 minutes).

After data has been entered and the analysis has been performed, the user is provided with a menu to choose output data to be plotted to the terminal using the PLOTLP plotting routine from Reference 7. Finally, plot files are created and written to user-specified output files. These plot files can be routed to the CALCOMP plotter using the PLOTM routine available through the Super Procfile available on the NOS operating system (2).

# PROGRAM ODEF15

```

C
C*****
C
C SIMULATION PROGRAM TO TEST A PI OR CGT/PI, WITH/WITHOUT KALMAN
C FILTER, BASED ON A 4-STATE MODEL OF THE STOL F-15. OPTIONS
C INCLUDE MODIFICATION OF DYNAMICS MATRIX, USE OF 2-STATE
C ACTUATOR MODELS, APPLICATION OF RATE/POSITION LIMITS ON ACTUATORS,
C AND EMPLOYMENT OF ANTI-WINDUP COMPENSATION. USER SUPPLIES DYNAMICS
C MATRIX, OUTPUT MATRIX, CGT COMMAND MODEL, CONTROLLER GAINS AND
C KALMAN FILTER MATRICES.

Appendix D: Derivation of Nonlinear  
Thrust/Nozzle Model

The following is a derivation of the STOL F-15 aircraft model using both thrust (throttle) and nozzle deflection as inputs to the system. As will be seen in this derivation, the simultaneous control of these two quantities introduces a nonlinearity into the system model. Efforts were made to design a constant-gain controller for this system; however, instability proved to be a severe problem which could not be overcome. To allow the use of both throttle and thrust vectoring nozzles in flight requires that either a proper linearization of this model be derived or that extensions to the constant-gain CGT/PI/KF be introduced to compensate for this nonlinearity.

For Figure D.1, the X direction force, Z direction force, and longitudinal moment equations become:

Fig. D.1. Diagram of Nozzle Deflection

$$f_{T_X} = \frac{T}{m} \cos \delta_N \simeq \frac{T}{m} \quad (D-1)$$

$$f_{T_Z} = T \sin \delta_N \simeq T \delta_N \quad (D-2)$$

$$M_{T_z} = \ell f_{T_Z} \simeq \ell T \delta_N \quad (D-3)$$

respectively, where  $m$  is the aircraft mass. Also note that small angle approximations are made in Equations (D-1) and (D-2).

Incorporating (D-1) and (D-2) into the standard perturbation equations of motion (in dimensional derivative form) (19) yields:

$$\dot{u} = -g\theta \cos \theta_0 + X_u u + X_\alpha \alpha + X_{\delta_S} \delta_S + \frac{T}{m} + X_{\delta_C} \delta_C \quad (D-4)$$

$$\begin{aligned} \dot{w} - u_0 q = -g\theta \sin \theta_0 + Z_u u + Z_\alpha \alpha + Z_{\dot{\alpha}} \dot{\alpha} + Z_q q \\ + Z_{\delta_C} \delta_C + Z_{\delta_S} \delta_S + \frac{T}{m} \delta_N \end{aligned} \quad (D-5)$$

$$\begin{aligned} \dot{q} = M_u u + M_{T_u} u + M_\alpha \alpha + M_{\dot{\alpha}} \dot{\alpha} + M_q q + M_{\delta_S} \delta_S \\ + \frac{\ell T}{I_{YY}} \delta_N \end{aligned} \quad (D-6)$$

Now, taking the Laplace transform of (D-4) to (D-6), again invoking small angle approximations, and using the approximation that the acceleration in the  $z$  direction is equal to

the forward velocity times the derivative of the angle of attack:

$$\dot{w} \approx u_o \dot{\alpha} \quad (D-7)$$

Equations (D-4) to (D-6) become:

$$su = -g\theta + X_u u + X_{T_u} u + X_\alpha \alpha + X_{\delta_S} \delta_S + X_{\delta_C} \delta_C + \frac{T}{m} \quad (D-8)$$

$$s\alpha u_o - u_o q = -g\theta\theta_o + z_u u + z_\alpha \alpha + s z_{\dot{\alpha}} \dot{\alpha} + z_q q + z_{\delta_S} \delta_S + z_{\delta_C} \delta_C + \frac{T\delta_N}{m} \quad (D-9)$$

$$sq = M_u u + M_{T_u} u + M_\alpha \alpha + M_{T_\alpha} \alpha + s M_{\dot{\alpha}} \dot{\alpha} + M_q q + M_{\delta_S} \delta_S + M_{\delta_C} \delta_C + \frac{l_T \delta_N}{I_{yy}} \quad (D-10)$$

Upon rearranging (D-9), it becomes:

$$s\alpha = \frac{u_o q}{(u_o - z_{\dot{\alpha}})} - \frac{g\theta\theta_o}{(u_o - z_{\dot{\alpha}})} + \frac{z_u u}{(u_o - z_{\dot{\alpha}})} + \frac{z_\alpha \alpha}{(u_o - z_{\dot{\alpha}})} + \frac{z_q q}{(u_o - z_{\dot{\alpha}})} + \frac{z_{\delta_C} \delta_C}{(u_o - z_{\dot{\alpha}})} + \frac{z_{\delta_S} \delta_S}{(u_o - z_{\dot{\alpha}})} + \frac{T\delta_N}{m(u_o - z_{\dot{\alpha}})} \quad (D-11)$$

In state space form, the original aircraft equations of motion are of the form:

$$\begin{bmatrix} \dot{u} \\ \dot{q} \\ \dot{\alpha} \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ A_{21} & A_{22} & A_{23} & A_{24} \\ A_{31} & A_{32} & A_{33} & A_{34} \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} u \\ q \\ \alpha \\ \theta \end{bmatrix} + \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ B_{21} & B_{22} & B_{23} \\ B_{31} & B_{32} & B_{33} \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \delta_C \\ \delta_S \\ \delta_N \end{bmatrix} \quad (D-12)$$

Using the following first-order lag model for throttle dynamics (20)

$$\frac{I}{\delta_T} = \frac{K_T}{s + \frac{1}{\tau_T}} \quad (D-13)$$

and Equations (D-8), (D-10), and (D-11), the nonlinear model which incorporates both thrust and nozzle inputs, is formed as:

$$\begin{bmatrix} \dot{u} \\ \dot{q} \\ \dot{\alpha} \\ \dot{\theta} \\ T \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{13} & A_{14} & \frac{1}{m} \\ A_{21} & A_{22} & A_{23} & A_{24} & 0 \\ A_{31} & A_{32} & A_{33} & A_{34} & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \tau_T \end{bmatrix} \begin{bmatrix} u \\ q \\ \alpha \\ \theta \\ T \end{bmatrix}$$

$$+ \begin{bmatrix} B_{11} & B_{12} & B_{13} & 0 \\ B_{12} & B_{22} & [B_{23} + \frac{T}{m(u_0 - z_{\dot{\alpha}})}] & 0 \\ B_{31} & B_{32} & [B_{33} + \frac{\ell T}{I_{yy}}] & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \delta_C \\ \delta_S \\ \delta_N \\ \delta_T \end{bmatrix}$$

(D-14)

Note that (D-14) has been written in a form to make the linear terms and nonlinear terms obvious.

## Appendix E: Basic Kalman Filtering Theory

The following is a presentation of steady-state constant-gain Kalman filter theory. This is intended to acquaint the reader with the simple form of filter which was used in the controller presented in Chapter V. For a complete treatment of this topic, see Reference 11.

The Kalman filter is an optimal recursive algorithm which is used to produce estimates of system states based on partial, noise-corrupted measurements of the form:

$$\underline{z}(t_i) = \underline{H} \underline{x}(t_i) + \underline{v}(t_i) \quad (\text{E-1})$$

where  $\underline{H}$  is the system measurement matrix and  $\underline{v}$  is a zero-mean white Gaussian noise with associated covariance

$$E\{\underline{v}(t_i)\underline{v}^T(t_j)\} = R \delta_{ij} \quad (\text{E-2})$$

The mean and covariance of the states after a measurement are defined conditionally via Bayes rule (11:18) based on the systems measurement history,  $\underline{Z}(t_{i-1})$ , to be

$$\hat{\underline{x}}(t_{i-1}^+) = E\{\underline{x}(t_{i-1}) | \underline{Z}(t_{i-1}) = \underline{Z}_{i-1}\} \quad (\text{E-3})$$

$$P(t_{i-1}^+) = E\{[\underline{x}(t_{i-1}) - \hat{\underline{x}}(t_{i-1}^+)] [\underline{x}(t_{i-1}) - \hat{\underline{x}}(t_{i-1}^+)]^T |$$

$$\underline{Z}(t_{i-1}) = \underline{Z}_{i-1}\} \quad (\text{E-4})$$

Once the update of the state estimate and covariance is accomplished, these quantities are propagated to the next sample time to attain the conditional mean and covariance at that time, before measurement update, defined as

$$\hat{\underline{x}}(t_i^-) = E\{\underline{x}(t_i) | Z(t_{i-1}) = Z_{i-1}\} \quad (E-5)$$

$$\underline{P}(t_i^-) = E\{[\underline{x}(t_i) - \hat{\underline{x}}(t_i^-)][\underline{x}(t_i) - \hat{\underline{x}}(t_i^-)]^T | Z(t_{i-1}) = Z_{i-1}\} \quad (E-6)$$

Based on the above equations, the Kalman filter equations are shown to be (11):

$$\hat{\underline{x}}(t_i^-) = \underline{\phi} \hat{\underline{x}}(t_{i-1}^+) + \underline{B}_d \underline{u}(t_{i-1}) \quad (E-7)$$

$$\underline{P}(t_i^-) = \underline{\phi} \underline{P}(t_{i-1}^+) \underline{\phi}^T + \underline{G}_d \underline{Q}_d \underline{G}_d^+ \quad (E-8)$$

$$\underline{K}(t_i^-) = \underline{P}(t_i^-) \underline{H}^T [\underline{H} \underline{P}(t_i^-) \underline{H}^T + \underline{R}]^{-1} \quad (E-9)$$

$$\hat{\underline{x}}(t_i^+) = \hat{\underline{x}}(t_i^-) + \underline{K}(t_i) [\underline{z}_i - \underline{H} \hat{\underline{x}}(t_i^-)] \quad (E-10)$$

$$\underline{P}(t_i^+) = \underline{P}(t_i^-) - \underline{K}(t_i) \underline{H} \underline{P}(t_i^-) \quad (E-11)$$

It is this form of the Kalman filter which is used to replace the assumption of full state availability with estimates produced as in Equation (E-10) for the designs presented in Chapter V.

## Appendix F: Plotted Data for Section 5.7

### Introduction

The following plots correspond to the robustness analysis conducted in the course of this thesis (see Section 5.7). Each plot contains the time histories of the pitch angle, flight path, and pitch rate channels along with throttle, canard, and stabilator deflections over a 6-second period.

Fig. F.1. Aircraft Response with Actuators, Position Limits, and Kalman Filter in the Loop/Throttle Absolute Value Function

Appendix G: Notes on LTR Technique for Application  
to LQG/PI/KF System

In this appendix, some ideas which have been generated concerning LTR tuning and its application to the designs used in this thesis will be presented. No definite conclusions will be presented in this appendix; however, some suggestions which may be worth pursuing will be introduced.

At the onset of using the LTR technique in this thesis effort, Equation (4-4) was applied in a rather blind fashion. When results showed no improvement in the system robustness, the assumption was made that, perhaps, the LTR tuning technique was not applicable to the LQG/PI/KF controller structure which was implemented in the designs presented in Chapter V. Following the apparent failure of the LTR technique, the ad-hoc C-tuning method was attempted and system robustness was greatly enhanced. After a more detailed investigation of the LTR method (G1:G2), three conclusions have been reached concerning the above-mentioned results:

1. The fact that LTR tuning based on Equation (4-4) did not improve system robustness simply implies that the system robustness characteristics for the loop broken at the input are not desirable in the full state case.

Therefore, as  $q$  was increased, the filter-based system asymptotically approached what could have been poor robustness characteristics in the non-filter-based system.

2. The favorable results obtained using C-tuning is completely reasonable under existing LTR theory. As stated in Reference G.1, robustness enhancement can be obtained at any arbitrary break in the controller loop by injecting white noise into that point in the system. Therefore, the C-tuning roughly corresponds to LTR tuning applied with the system broken at the output. Based on the preceding, an explanation for the success of the LTR method applied at the output instead of the input of the system indicates that the full state controller displays better robustness characteristics in the variables of interest to us in this application than the system broken at the input, and it is these loop transmission characteristics that are recovered.

3. The above assumptions should be investigated using computer analysis of the frequency response of the system broken at both the input and output to verify that indeed the injection of white noise into the outputs of the design model is the proper form of the LTR tuning technique to be used in this particular flight control design. Once the proper point to regain system loop transmission robustness is established (perhaps not even the input or the output points, but some other point in the loop), the LTR

technique can be applied and structured singular value analysis could be used to establish the amount of recovery which is achieved as  $q$  is increased.

Based on the fact that what is referred to as C-tuning is really LTR tuning, it has been shown that, in fact, LTR tuning is applicable to a CGT/PI/KF control structure. The problem which remains to be solved is the fore-mentioned task of determining the proper point in the loop to break the loop, or at least to show that the loop transmission robustness characteristics of the system broken at the output do indeed display favorable frequency response characteristics (i.e., bandwidth, crossover frequency slope, etc.).

## VITA

Robert Houston was born on 24 February 1961 in Dallas, Texas. He graduated from high school in Somerset, Texas in May 1979, and enlisted in the United States Air Force in July 1979. He attended Basic Military Training School and Security Specialist training at Lackland Air Force Base, Texas. Upon graduation from technical training he attended Air Base Ground Defense combat school at Camp Bullis, Texas. From December 1979 to June 1980, he served as a close-in security sentry guarding B-52, KC-135, and EC-135 alert aircraft at Ellsworth Air Force Base, South Dakota. In June 1980 after attaining the rank of Airman First Class, he was selected for Airman Scholarship and Commissioning program and enrolled in the Reserve Officers Training Corps at the University of Texas at Austin. Upon graduation with a degree in Electrical Engineering in May 1984, he was commissioned a second lieutenant in the United States Air Force Reserve. He entered the School of Engineering of the Air Force Institute of Technology in May 1984 and has pursued the Guidance and Control curriculum of the Electrical Engineering Department.

A robust controller for the STOL F-15 aircraft is developed using the LQG/LTR (linear system model, quadratic cost, gaussian models of uncertainty used for controller synthesis, with loop transfer recovery techniques of tuning the filter in the loop for control robustness enhancement) methods. Full state feedback controllers are synthesized using CGT/PI (Command Generator Tracking feedforward compensator to provide direct incorporation of flying qualities into the design process, with proportional plus integral feedback control) synthesis, using implicit model following techniques to improve full state robustness characteristics. Finally, a Kalman filter is used to replace the unrealistic assumption of full state availability with estimated states, using a LTR scheme to recover as much full state robustness characteristics as possible.
